It is announced in the *Times* of August 28 that Prof. A. G. Green, director of research of the British Dyestuff Corporation, has resigned his post on account of "dissatisfaction at the lack of technical knowledge on the board of directors, and his belief that the permanent establishment of the dyestuff industry in this country is impossible under these conditions." In Great Britain it is common for power to be in the hands of people without the scientific knowledge essential to make the best use of it for industrial and social progress; and Prof. Green has proved by experience what has often been pointed out in these columns and publicly stated by scientific workers in various industrial fields. In political appointments the same principle is adopted of placing the power over scientific departments in the hands of politicians without regard to their scientific knowledge or training. Sir William Joynson Hicks has, for example, just been appointed to succeed Mr. Neville Chamberlain as Minister of Health—this being the fourth Government post he has occupied in less than a year. Though it is accepted that a Chancellor of the Exchequer should know something about finance and a Solicitor-General something about law, apparently a Minister of Health need not know anything about science in order to control the manifold activities of a department mainly concerned with scientific problems.

A sensational report of a change of level of the bed of the Atlantic between Cape Town and St. Helena was made on the authority of the Eastern Telegraph Co. last week. It was stated that a cable repair-ship found a depth of three-quarters of a mile at a place where the chart showed a depth of three miles when the cable was laid in 1899. Changes of level of the ocean floor have often been brought to light by soundings, but the actual rise or fall is reckoned in a few feet or fathoms, and nothing of such a stupendous character as a change of more than two miles has ever been established by surveys. Decrease of depth could, of course, be caused by accumulation of the products of an eruption of a submarine volcano, and in such an event the rise of level would be local and the material would soon be worn down. Both Vesuvius and Etna began their careers as submarine volcanoes, and Sir Archibald Geikie records a number of submarine eruptions in his "Text-book of Geology," though nothing approaching the building of such a pile as would be required to produce the difference of level reported above. All that can be said at present, therefore, is that an actual uplift of the dimensions reported in so short a time is unthinkable and that the accumulation of volcanic material to produce the change of depth is extremely improbable. Confirmation of the accuracy of the old sounding as well as of the new will be required before any scientific significance can be attached to the report.

Several experiments have been made recently, both in America and in France, to instal a complete radio telephonic set in express trains. In the fast express train between Hoboken and Buffalo this has been done. Passengers can continue conversations with their friends which were interrupted by the train starting; they can also receive radio telegrams from their friends while the train is in motion. In *La Nature* for August 18, a technical description is given of the experiments which have been carried out by three of the French railway companies in making such "concert" cars. On the Paris-Orléans railway, the experimental saloon cars had two loud-speaking telephones fitted at each end of the cars. Up to a distance of 210 miles from Paris, the Eiffel Tower concerts were heard quite satisfactorily. As a rule the concerts were better heard than the news items. When the train goes through deep cuttings the sound is notably reduced, and when going through long tunnels it almost disappears. As there are at present only three large broadcasting stations in the neighbourhood of the railway, and as these are near Paris, the concert cars have only a limited use. With the arrangements used it was found that the large radio telegraphic stations near the Bordeaux-Paris line produced serious disturbances. When going round curves also, discordant sounds were heard due to the friction of the flanges of the wheels on the rails.

"Climbing Mount Everest," the cinematograph record of last year's attempt to scale the world's highest peak, was presented in a revised edition with several new photographs on August 27 at the Polytechnic Hall, London. Capt. J. B. L. Noel, who took the photographs, provided an interesting running commentary as the pictures appeared, while the orchestra played "Airs of Tibet and Nepal," collected in Tibet by Mr. J. Howard Somervell, one of the party of four who made the first attack on the summit. Frankly an entertainment of great and vital interest, designed to raise funds for an attempt on the peak in 1924, this pictorial account of the greatest achievement in mountaineering has been wisely chosen by Natural Films, Ltd., to inaugurate by a four weeks' season the series of travel and interest films which are to be presented to Londoners at this hall during next winter. While Capt. Noel deliberately emphasised merely the sporting nature of the climbing effort, his pictures show a much wider outlook; of particular scientific interest are pictures of the land forms and the force of the prevalent westerly winds, and also of the customs and ceremonials of the Tibetans.

The fourth annual report of the Tidal Institute of the University of Liverpool describes further developments in the work of this vigorous young institution, though much of the work referred to is not yet ready for publication. Only a few of the more interesting features can be mentioned here. A study of the effect on the sea-level at Liverpool, of winds operating in the Irish Sea and in the Atlantic Ocean respectively, shows that their importance is in the ratio of about 2 : 3. The purely local winds seem to be less important than was hitherto supposed.

The Institute has undertaken the analysis of records for the Australasian Antarctic Expedition, 1911–1914, the Cope Antarctic Expedition, and the Gold Coast Survey. It has also prepared for the Admiralty a chart of co-tidal and co-range lines in the North Sea constructed on a new plan, namely, by calculation from the tidal current data, using the dynamical equations which connect the currents with the surface gradients. Similar methods have been applied to the tides of the northern portion of the Irish Sea. Much work has also been done on the more purely mathematical branches of tidal theory.

THE work of the National Institute of Agricultural Botany at Cambridge, though only started in the new buildings in 1921, has made sufficient progress to justify the issue of an annual journal embodying the chief scientific results obtained year by year. In the first number the director reports on the potato maturity and yield trials, from which it is already possible to draw trustworthy conclusions in spite of disturbances to the results brought about by such factors as the use of seed tubers drawn from different districts, and in some cases affected with virus disease. The barley trials, however, do not as yet warrant the publication of a detailed account, owing to unfavourable weather conditions during 1922, but it is hoped that by the end of the next season it will be possible to make a critical analysis of the experimental results. The included fifth annual report of the Official Seed Testing Station indicates that much wider use is being made of the facilities provided, 25 per cent. more persons having submitted samples, the increase in the number received from farmers being 35 per cent. An interesting innovation was a course of training in seed testing, followed by practical and theoretical examinations, several of the candidates being nominated by various seed firms. The journal (which may be obtained from the Secretary of the Institute, Huntingdon Road, Cambridge, price 1*s.* 1*d.* post free) concludes with the report of the Potato Synonym Committee and a synopsis of recent work on leaf roll and mosaic of the potato in Ireland, read before a special meeting of fellows of the Institute.

AN interesting note by Dr. R. C. Benedict upon laws introduced by various States in U.S.A. to protect rare wild plants is published in *Science* for July 20. More than forty species of wild ferns and flowering plants are protected in Vermont by an act passed in 1921; Connecticut legislated to protect the climbing fern, *Lygodium palmatum*, so long ago as 1867, and has since introduced new statutes extending the list of protected plants; it has also enacted that shipments of wild plants, legally sold as from private land, must bear definite indications of their source, while written permission from the landowner must be filed with the county officers. California protects the Toyon berries (*Heteromalis arbutifolia*) so much in demand for Christmas decoration, while practically all the wild flowers of Yosemite are protected. Massachusetts has also passed a comprehensive law, and Dr. Benedict quotes with approval the text of a plant protection law recently proposed in Illinois. The many plant lovers interested in legislation to protect British wild plants would probably find the numerous legislative experiments in this direction made by the different States a valuable source of information on the subject, especially if trustworthy information can also be obtained as to the degree of success obtained. Dr. Benedict states that evidence from both botanical and commercial sources indicates that the Vermont legislation has proved effective. Some laws have probably been badly drafted; Dr. Benedict emphasises the fact that the plant must be treated differently from the migratory animal; it belongs to the land on which it grows and, except perhaps in the case of infectious disease or poisonous plant, the State may not restrict the farmer's operations upon the land.

AT the third annual meeting of the British Chemical Plant Manufacturers' Association, held in London on July 18, the chairman (Mr. L. M. G. Fraser), in moving the adoption of the annual report, directed attention to the principal aims and activities of the Association. He said that a great deal of work has been carried out by its committee in standardising various types of chemical plants, and that consequently manufacturers have altered their patterns at considerable trouble and expense, for the ultimate advantage of chemical manufacturers. Also, the properties of chromium steel have been thoroughly investigated, and it is hoped that a continuance of the work will lead to a satisfactory solution of some of the problems connected with the use and manipulation of the alloy in the construction of chemical plant. The technical chemist is constantly needing vessels capable of withstanding higher temperature and pressure than ever before, and the Association is fully alive to the importance of watching and following up the results of metallurgical research into suitable alloys for such purposes. In particular, need is felt for further technical research on the part of ironfounders into cast-iron, with the view of obtaining a closer grained and stronger metal more capable of resisting corrosion by electrolytic action. It is hoped that the Association will be represented on the Cast-Iron Research Association and other similar research organisations. An interim report has been presented to the Association of British Chemical Manufacturers upon the training of chemical engineers, which is full of difficulties in regard not only to the framing of a curriculum but also to persuading educational authorities to adapt their methods to new requirements. The tendency of present-day education is to be too intensive; a much broader training would be of far more use to the majority of men. It is to be regretted that, owing to insufficient support being forthcoming, the Association will not participate in the Chemical Section of the British Empire Exhibition next year.

WE regret to announce the death on August 26 of Mrs. Hertha Ayrton, well known in the scientific world for her researches on the physics of the electric arc and other subjects.

DR. GEORGE H. PETHYBRIDGE, until recently head of the Seeds and Plant Disease Division of the Department of Agriculture and Technical Instruction for Ireland, has been appointed mycologist to the Ministry of Agriculture and Fisheries for England.

DR. C. E. K. MEES has described, in the Journal of the Franklin Institute for August, the way in which the Eastman Kodak Company has sought to overcome the chief difficulties that prevent "motion photography" from being available for general purposes, reducing the cost and facilitating the development, etc., of the film. The "Cine Kodak" weighs about 8 pounds and takes 100 feet of film, which is equivalent, with its smaller pictures, to 250 feet of film of the standard size. The projector is driven by a motor so that it is automatic, and has a capacity for 400 feet of film, which requires 16 minutes to show on the screen. A large saving is effected in the cost of the film by its smaller size, and a further economy is gained in the majority of cases where only one film of the subject is required, by treating the exposed film by a reversing process, instead of making the positive by printing it on a second film. But "this is quite a complicated process and requires very special and complicated equipment" to avoid the appearance of graininess on the screen, so the Company undertakes this work itself. By these means the fifteen cents per second of picture as shown on the screen, which is about the cost of a standard film, is reduced to two and a half cents per second; and as 7 or 8 seconds is a sufficient duration of exposure for a single scene (such as a waterfall or a game), the cost for one subject is about 20 cents, and this compares favourably with the cost of making a negative and one print in the ordinary way. The film base is made from cellulose acetate, so that the risk from fire that the ordinary film of cellulose nitrate suffers from is practically done away with.

A NEW edition of his work on "The Endocrine Organs" is being prepared by Sir E. Sharpey Schafer for publication by Messrs. Longmans and Co. Part 1, dealing with the thyroid, parathyroids and suprarenals, will appear this autumn, and Part 2, embracing the rest of the subject and completing the work, next year.

Our Astronomical Column.

THE TOTAL SOLAR ECLIPSE OF SEPTEMBER 10.—This eclipse is total in south-west California and the adjacent islands; also in Mexico. There is no official expedition from the British Isles, but many of the great American Observatories are sending parties to observe it. *Popular Astronomy* for June-July contains an outline of their programmes. The Yerkes, Washburn, and Goodsell Observatories are occupying Catalina Island. The Washburn party will measure the brightness of the corona by the photo-electric cell; the Goodsell party will photograph the corona and star-field with an 8-inch lens, and the flash spectrum with a grating.

Mt. Wilson and Leander McCormick Observatories will occupy two stations; at Point Loma the corona and star-field will be photographed, also the spectra of corona and chromosphere; the interferometer will be used to determine the wave-length of the green coronal line and the rotation period of the corona. Their other station is at Lakeside, near the northern limit of totality, where the flash spectrum will be photographed with concave gratings.

The Lick Observatory, and the Students' Observatory of the University of California, will work together at Ensenada. The polarisation of the coronal light will be measured, and many other researches made.

The Sproul Observatory is occupying Cuencame, Mexico, and will photograph the corona both on a large and a small scale; also the flash spectrum. The interferometer will be used to study the rotation of the corona.

The University of Toronto will study the spectrum and polarisation of the corona.

The Steward Observatory (University of Arizona) and the Mexican National Observatory will also occupy stations in Mexico.

The Lick Observatory will not repeat the Einstein investigation, believing that the question was sufficiently settled at the eclipses of 1919 and 1922. The Goodsell, Mt. Wilson, and Sproul Observatories will take star photographs for this purpose, though the star-field is a poor one—less suitable than those of 1919, 1922. Signor Emanuelli, of the Vatican Observatory, gives a list and diagram of the stars in the region in *Astr. Nach.* There are three stars (magnitudes 8·8, 8·5, 8·0) with Einstein displacement exceeding 1″; they are likely to be hidden in the corona: six stars with displacements between 1·0″ and 0·6″ (magnitudes 8 to 9); thirteen stars between 0·6″ and 0·4″; fifty-eight stars between 0·4″ and 0·2″. Some of these last are fairly bright, one being σ Leonis.

INTERNAL MOTION IN THE SPIRAL NEBULA MESSIER 33.—Mr. A. van Maanen contributes another of his important papers on internal motion in the spiral nebulæ to the *Astrophys. Journ.* for June.[1] The measures were made on pairs of plates taken with the 60-inch reflector, the time interval being 12 years; 24 comparison stars and 400 points presumably belonging to the nebula were measured. One of the latter shows an annual displacement of 0·136″, so that its connexion with the nebula is disproved. The remaining points when plotted show consistent motions outwards along the arms of the spiral. The mean annual motion of the nebula as a whole, relatively to the comparison stars, is +0·003″ in R.A., −0·004″ in decl. The motions of the nebular points, in addition to their outward movements, indicate rotation in periods varying from 60,000 years for the inner portions to 240,000 years for the outer ones. The mean component of velocity along the nebular stream is +0·020″; it increases slightly as the distance from the centre increases.

Mr. van Maanen gives in full the reasoning which leads to the conclusion that these displacements are real. Taken in conjunction with the radial velocities measured, they indicate a parallax of the nebula of the order of 0·0005″, or a distance of 6000 light-years. The diameters of the spirals are many light-years (in some cases hundreds of light-years), but they are much smaller objects than the Galaxy.

Research Items.

SKELETON FROM AN ANCIENT WORKING IN RHODESIA.—In the Proceedings of the Rhodesia Scientific Association, vol. xxi., 1922–23, Mr. G. Arnold publishes a report by Sir Arthur Keith on a skeleton found in an ancient working near the Gwanda Mine. Sir Arthur Keith thinks that the skeleton may be ten centuries old. The remains are those of a young woman about 20 years old, and the character of the face and cranium show that she was a negro of the type so often seen among Matabele and Zulu women. It is to be remarked that the outer margins of the crowns of the more anterior teeth have been chipped during life, as if hard nuts or bones had been cracked in the mouth. One remarkable feature is the non-development of the upper wisdom teeth: they have never been formed, a common occurrence among European women, but uncommon among negroes.

A SAXON GOLD RING FROM YORKSHIRE.—Many years ago the late Canon Greenwell informed Mr. T. Sheppard, Curator of the Hull Museum, that a massive gold ring had been found in a Saxon burial ground near Driffield, East Yorkshire. Inquiries were made from a person who was believed to hold it, but in vain, until recently it appeared in the window of a Piccadilly jeweller, whence it was purchased for the Hull Museum. It weighs 15 grains and has a large oval bevel, in the centre of which is a fine garnet held by a plate of gold; the face of the ring is decorated with ornamentation made of fine gold wire. This seems to be the third record of a ring of this type, other specimens being deposited in the Ashmolean and British Museums—the two latter rings bearing the inscription "Nomen Ehlla Fides in Christo." Objects of a similar type are described by Mr. Sheppard in pamphlet No. 134 of the useful series issued by the Hull Museum.

THE EASTER ISLAND STATUES.—The interest of archæologists has been excited by the account by Mrs. Routledge of the remarkable statues of Easter Island. Mr. H. G. Beasley, in the August issue of *Man*, describes an image only 9¾ inches high, which he was lucky enough to pick up at a shop on the Continent. It seems to be of the technique of the Easter Island statues, the material being a piece of volcanic ash, once covered with red ochre, which appears to be the effigy of some worthy, in honour of whom it was smeared with red, like images in India, the red being the survival of a blood sacrifice. The domed head of the image is remarkable, as Mrs. Routledge found only one example of this type in the course of her excavations. Her inquiries show that, in addition to the great statues raised on platforms in Easter Island, a variety of smaller stone objects were made for personal use, and as niches are found in the inner walls of the houses, small images such as this may have been placed therein.

THE EVOLUTION OF THE PALÆOZOIC FLORA.—In recent years considerable attention has been given by botanists to the lines along which the Upper Devonian flora developed, and the characters of the Middle Devonian flora of the cherts of Rhynie in Aberdeenshire have given attraction and urgency to research into still older plant-remains. This point is emphasised by Dr. A. C. Seward as president of the Geological Society of London, in his address published in the Quarterly Journal of that Society for July, 1923 (vol. 79, Proc., p. lxvi). Unfortunately, he can hold out but little hope of terrestrial plant-remains of pre-Devonian age. Vegetation still clung to the swampy fringes of the continents and islands until the epoch of the Rhynie beds. It was not till Upper Devonian times (p. ciii) that it "had come into its own, and had colonized the higher and drier ground." The "change in the geological background had its reflex in the development of green foliage in place of the almost leafless condition of the older plants." The rest of this sentence ("destined to live in localities either physically or physiologically dry") seems to have got somehow out of place. In dealing with the Archæopteris flora, Dr. Seward asks how such plants were adapted to survive the long months of arctic darkness; but he feels that we are not yet "in a position to demand as a necessity either a shifting axis or a wandering crust." The critical horizon indicated by the Rhynie peat-bog has been discussed by F. O. Bower and D. H. Scott (NATURE, vol. 105, p. 681, 1920, and vol. 108, p. 153, 1921); and Dr. Scott has recently contributed a paper on the early history of the land floras (vol. 110, p. 606, 1922), which should be compared with Dr. Seward's address. Dr. Seward, however, carries the survey farther back, and reviews evidence that is rarely brought together as a whole. He remarks (p. lxxv) that Cryptozoon may be the skeleton of an animal, but is not a plant. Dr. O. Holtedahl has always viewed this genus and its allies with suspicion (*Amer. Journ. Sci.*, 4th ser., vol. 47, p. 85, and vol. 201, p. 195; see NATURE, vol. 103, p. 330, and 107, p. 795), and Dr. Seward has come independently to his conclusion that a comparison of its nodular masses with those formed of calcite in the Magnesian Limestone of Durham is fully justified. It seems that Cryptozoon, with its allies from Huronian to Carboniferous strata, is destined to go the way of Eozoon.

CRYSTAL CLEAVAGE AND CRYSTAL STRUCTURE.—Under the above title, Mr. Maurice L. Huggins has published in the *American Journal of Science* (vol. 206, p. 203, 1923) a number of diagrams and descriptions of crystal-structure, showing the probable position of electrons along lines representing bonds between the atoms, and he concludes that (i.) cleavage tends to occur so as to leave two new crystal surfaces that are electrically neutral; (ii.) if some bonds in the crystal are weaker than others, cleavage ruptures the weaker bonds in preference to the stronger ones; (iii.) if all the bonds are equally strong, cleavage will occur between the planes connected by the fewest bonds per unit area of the cleavage plane. Readers of NATURE have had their attention directed to the question of crystal strength and crystal weakness in Sir William Bragg's recent paper on crystal analysis (Supplement, June 9, 1923, p. v). Mr. Huggins conceives, however, that the splitting of a crystalline structure occurs between an atomic kernel and a group of electrons, or between two electron groups or two electrons in a pair, rather than merely between two atoms or planes of atoms. A simple illustration is seen in the two-dimensional diagram of bismuth structure in Fig. 7. The risk that we run—we who are not gifted with transcendental powers of introspection—seems to lie in regarding the circular atomic nuclei, and the smaller electron circles, in such diagrams as known physical entities, instead of as points at which something happens.

AN ANTARCTIC METEORITE.—The latest to be issued of the scientific reports of the Australasian Antarctic Expedition, 1911–14 (series A, vol. 4. pt. 1), is devoted to a description of the Adelie Land meteoric stone. The finding, on December 5, 1912, about twenty miles west of Cape Denison, of this small black object resting

on Antarctic snow was a remarkable chance. How many times since its fall from the skies it may have sunk beneath the surface by absorption of summer heat, to be exposed again by ablation, who can tell? The description by F. L. Stillwell, and very detailed chemical analysis by P. G. W. Bayly, show that the stone, which weighed originally $2\frac{1}{4}$ lb., is an "intermediate hypersthene-chondrite" containing about $6\frac{1}{2}$ per cent. of nickeliferous iron.

HOT WAVES IN THE UNITED STATES.—*The Scientific Monthly* for August contains an article by Prof. R. de C. Ward, of Harvard University, on "Hot waves, hot winds and *Chinook* winds in the United States." The subject is dealt with scientifically, and the meteorological aspect is rendered of considerable interest by the graphic descriptions introduced. Hot waves or spells of excessive hot weather occur at irregular intervals, and continue for varying periods of time; they are somewhat common to the summers of the central and eastern United States. A hot wave has not acquired the official definition similar to that attached to a cold wave. The heat is caused by the southerly and south-westerly winds that prevail in the front of a weak cyclonic depression as it moves slowly eastwards across the northern tier of states, and the air, coming from warmer latitudes, causes high temperatures, accompanied by high humidity and generally hazy skies. Under the high and powerful sun the thermometer may rise well into the 90's and even to 100° F. The night is likely to bring little relief except in the mountains and on the coast, and the minimum temperatures are often over 70° F. Occasionally two, or even more, hot waves come in succession with little interruption. A prolonged hot wave is commonly accompanied by drought. Hot waves are most pronounced in July, but they are often severe in August and September, and maturing crops are often injured. A detailed description is given of *Chinook* winds, which are distinctly of the *föhn* type, and are commonly experienced along the eastern base of the Rocky Mountains; in these a rise of temperature from below zero to 40° F. or 45° F. in a few hours is sometimes experienced.

EFFECT OF WIND DIRECTION AT JERUSALEM.—The Ministry of Public Works, Egypt, has recently issued a discussion, Physical Department paper No. 10, by Mr. S. Krichewsky, on "Effect of wind direction on temperature and humidity at Jerusalem." The author quotes Biblical passages showing the effect of the different winds of Palestine. He also refers to modern information by Dr. Chaplin, who made meteorological observations at Jerusalem from 1861 to 1883. Statistical research is now made by the author, using observations from 1896 to 1913 by the Deutsch Palästina Verein published in the "Wiener Met. Jahresberichte." Observations are used for 7, 13, and 21 hours daily. The north wind which has been described as cold only causes the mean temperature to be lower in the winter than when winds are blowing from other directions; in other seasons of the year the mean temperature of this wind is above the normal; as a rule north winds are rare. The south wind is more rare than the north wind, and it seldom blows in summer; it is chiefly in spring that a south wind is warm. The east wind is reputed to be hot and very dry, its humidity is always below normal, it is rare in summer but very frequent in winter. The east wind is the principal factor of drought and it generally raises the mean temperature above normal, especially in spring when the desert winds turn into *Sirocco*. The west wind is damp as naturally as the desert wind is dry; it is the most important wind of Palestine, and supplies water vapour which produces rain or dew; the west is the most frequent wind throughout the year. The west wind is the real factor of coolness in spring, summer, and autumn.

THE ACCURACY OF VISUAL OBSERVATION AND MEASUREMENT.—The effect of the physiological properties of the eye on the accuracy of measurement is considered in a comprehensive paper by Dr. H. Hartridge appearing in the *Philosophical Magazine* for July. On purely optical grounds it is deduced that for white light and a 3 mm. pupil the images of two objects formed on the retina must be separated by $2\cdot9\ \mu$ in order that they shall be resolved by the eye. The size of the foveal cones imposes a histological limit of $3\cdot2\ \mu$, in fair agreement with the first estimate. The limit to the resolving power obtained by actual experiments is not very different from this figure, results varying between $3\cdot6\ \mu$ and $4\cdot6\ \mu$ being obtained by using test objects of various types. An improvement of roughly 15 per cent. has been obtained by substituting pure green light for daylight. The visual acuity of the eye for the positions and movements of contours is nearly ten times greater than it is for the resolution of double points, and lines. For the movement of a contour to be perceived it must cause a cone on one side of the edge of the image to receive an appreciably stronger stimulus, and that on the other an appreciably weaker one, than before. The acuity of the eye will therefore depend less on the diameter of the cone than on its ability to perceive small changes in light intensity. Various types of linear measurements are considered in detail. The method of coincidences, as in the measurement of an object by a scale and vernier, is found by experiment to give very accurate results. The error in the setting of the image on the retina is less than $0\cdot76\ \mu$, corresponding to 10 seconds of arc. The interpolation method of measurement, as used in the slide-rule, is much less accurate. The errors to which these methods are liable are discussed by Dr. Hartridge, and the means of avoiding them is described. Attention is also directed to the contact method of measurement, and to measurements of depth and distance, colour and intensity.

FULLER'S EARTH.—A survey of the fuller's earth industry appears in the *Chemical Trade Journal* for July 27. The two main producers of this mineral are America and England, the whole production of the latter country coming from Somerset and Surrey. The article gives a critical survey of the properties, applications, and preparation of the mineral for the market.

THE EINSTEIN DISPLACEMENT OF SOLAR LINES.—According to Einstein's relativity theory, each line in the spectrum of an element on the sun should be displaced towards the red from its position for a terrestrial source by an amount equivalent to an increase of its wave-length of two parts in a million. In the June issue of the *Journal de Physique* M. F. Croze reviews the experimental evidence available and shows that though displacements of the order required are observed, they do not follow the prescribed law, but vary with the intensity of the line, and with the point on the sun from which the light originates. These deviations cannot be explained by the influence of pressure at the sun nor by the Döppler effect. The author is disposed to regard them as due to anomalous dispersion in the atmosphere of the sun, as suggested by Julius, and hopes to test this theory quantitatively by means of the observations now being made at Mount Wilson.

The Liverpool Meeting of the British Association.

Programmes of the Sections.

The provisional programmes of the various Sections of the British Association, for the meeting to be held at Liverpool on September 12-19, show that the meeting will be of decided scientific importance and interest. It will be noticed that a number of distinguished men of science from abroad are attending the meeting and taking part in discussions.

We are indebted to the Recorders of the Sections for the subjoined outline of arrangements made for sectional papers, joint discussions, lectures, excursions, and other means of recording progress and promoting critical consideration of methods, results, and principles.

Section A (Mathematics and Physics).

The proceedings in Section A this year give promise of being exceptionally interesting and valuable, mainly because an unusually large number of distinguished foreign visitors are expected to take part. Several countries will be thus represented; France, America, Denmark, and Holland. In addition to this, Canada will have representation in the sectional president, Prof. J. C. McLennan, whose address on "The Origin of Spectra" will form an opening for a series of papers on cognate subjects, "The Correspondence Principle," by Prof. N. Bohr, "Remarks on Quantisation," by Prof. P. Ehrenfest, and "The Structure of Atoms and their Magnetic Properties," by Prof. P. Langevin, whose promised visit will compensate for his inability to attend last year on account of illness. These papers will be taken on Monday, September 17.

On the first working day, Thursday, September 13, there will be a discussion, jointly with the Sections of Chemistry and Engineering, on "Cohesion and Molecular Forces," to be opened by Sir William Bragg. This will be followed by a paper by Prof. C. G. Darwin—who has just returned from Pasadena—in which he will describe the important recent work of Prof. A. H. Compton on the scattering of X-rays. The remaining principal item on the programme will be a sectional discussion on "The Spectra of the Lighter Elements" on Tuesday, September 18. This will be opened by the president, and contributions will be made by Prof. Bohr and Prof. A. Fowler, and, probably, Prof. R. A. Millikan.

Among the individual papers which will be read may be mentioned contributions by Sir O. Lodge on "Matter and Radiation," Prof. R. W. Wood on "The Effect of Weak Magnetic Fields on the Polarisation of Resonance Radiation," and Mr. G. Stead and Miss B. Trevelyan on "The Production of Triatomic Hydrogen."

There will be papers on meteorological subjects by Capt. D. Brunt and Mr. F. J. W. Whipple, and one by Dr. A. T. Doodson on tides in relation to meteorology. Papers relating to the mathematical representation of experimental results have been accepted from Mr. T. Smith, Prof. H. Levy, and Mr. H. W. Moore.

The afternoon of September 14 will be devoted to demonstrations, including Mr. W. M. Mordey's alternating magnetism experiments and Mr. S. G. Brown's "Frenophone" or friction-operated loudspeaker.

Section B (Chemistry).

The programme of Section B covers a wide range of subjects. The president, Prof. F. G. Donnan, will deal with the physical chemistry of interfaces, and the same subject will be followed into detail in a joint discussion between Sections B and I on membranes. A second joint discussion has been arranged with Sections A and G, the subject being cohesion and molecular forces. This will be opened by Sir William Bragg, Dr. Rosenhain, and Dr. A. A. Griffith, and an attempt will be made to bring together the physicists, the metallurgists, and the engineers in a consideration of the processes of rupture of metal test-pieces and similar matters.

There will be a group of papers on the theory of the atom, Prof. G. N. Lewis opening with an account of the chemical applications of the quantum theory, followed by Dr. Sidgwick on the Bohr atom and the Periodic Law, Dr. Coster treating the same subject from the spectroscopic side. Dr. Hevesy will give an account of his most recent work on the chemistry of hafnium. An echo of last year's discussion on photochemistry will be heard in the form of a note on the biochemical effects of polarised light from Prof. Baly's laboratory. Dr. E. F. Armstrong will open a discussion on enzymes, to be contributed to by Dr. K. G. Falk, and there will be notes on certain new points in the chemistry of cotton and of rubber. On the last morning of the meeting, Senator Ginori Conti will give an account, illustrated by slides, of the progress now being made in Northern Italy in the use of volcanic steam for technical purposes.

Other papers deal with the formation of precipitates, the functions of active hydrogen atoms in organic compounds, and the nature of the alumino-silicates. Liverpool being an important chemical centre, there will be a number of excursions of special interest to the Section.

Section C (Geology).

The Section will meet under the presidency of Dr. Gertrude L. Elles, whose address will be entitled, "Evolutional Palæontology in relation to the Palæozoic Rocks," and will, by her desire, be followed by a discussion. Local geology will figure largely in the programme: Prof. Boswell will give an address on the geology of the Liverpool district, and Sir Aubrey Strahan will open a discussion on the changes in the geography of the district during Pleistocene and recent times and their possible bearing on the development of Chester by the Romans and their total neglect of the now much superior waterway of the Mersey estuary. Other local papers are by Mr. C. B. Travis, on recent geological changes on the Northern Shore of the Mersey Estuary; Mr. T. A. Jones, on the Middle Bunter sandstones and their pebbles; and Miss M. Workman, on the Permian rocks of Skillaw Clough.

A discussion on metamorphism will be opened by Dr. J. S. Flett.

Other papers include Prof. Kendall on isostasy and the Pleistocene levels of Britain; Prof. Boswell on the geology of the East Denbigh Moors; Prof. Hickling on the tectonics of the Lancashire coalfield; Dr. R. L. Sherlock on British rock salt deposits; Mr. G. Slater on ice phenomena in Spitsbergen; Mr. K. W. Earle on the geology of the Windward and Leeward Islands; and Mr. C. P. Chatwin on a new gasteropod fauna from the Chalk.

Numerous excursions to places of geological interest will take place during the meeting, including an examination of the Upper Ordovician and Lower Silurian rocks of the Vyrnwy district and a whole day excursion to Holywell and other parts of Flintshire.

Section D (Zoology).

Prof. J. H. Ashworth, president of this Section, will take as the subject of his address "Modern Zoology: its Boundaries and Some of its Bearings on Human Welfare."

In drawing up the programme of the Section, Liverpool work in zoology, oceanography, and tropical medicine has been borne in mind. The whole of Friday, for example, will be devoted to marine zoology, comprising contributions from Dr. Johs. Schmidt, of Copenhagen, who will give a popular lecture on the scientific work of the Danish exploration steamer, the *Dana*, illustrated by cinematograph; from Dr. Mortensen and Mr. Kramp, both of Copenhagen; from Prof. Johnstone, on Rhythmic Change in the Plankton; from Prof. Dakin, who will discuss the theory of Pütter regarding animal nutrition; and from Mr. Storrow, Dr. Marie Lebour, Mr. Hardy, Mr. Carruthers, Mr. Clark and Mr. Chadwick.

On Tuesday morning there will be a series of papers bearing on the problem of the determination of sex, the contributors being Dr. Crew, Prof. Dakin and Mr. Burfield, Mr. Huxley and Prof. Carr-Saunders, Dr. Heslop Harrison, Mr. J. R. Baker, and Dr.Parkes. During one of the sessions, Prof. Hickson will open a discussion on the systematic position of the Nematoda, and Profs. MacBride and Goodrich, and Dr. Baylis, will take part in the discussion. Mr Huxley will give a semi-popular lecture on the physiology of development in the frog; Prof. Ashworth will make a contribution on the life-cycle of Rhinosporidium; Prof. Cole will explain some new points which he has brought to light in regard to the anatomy of Myxine.

Other contributors to the sectional proceedings will be Mr. J. T. Cunningham on the origin of adaptations; Prof. Poulton on a new case of mimicry; Dr. Heslop Harrison on polyhedral disease in the vapourer moths; Miss Dorothy Jackson on the Biology of a Braconid parasite of the pea-weevil; Mr. Peacock on parthenogenesis in saw-flies; Mr. Speyer on complex Aphid life-histories; Mr. Hewer on colour changes in the common frog; Dr. Baylis on the host-range of parasitic nematodes; Prof. Blacklock on two tropical disease-carrying flies; Prof. McIntosh on some points relating to polychaetes; Mr. Graham Cannon on the post-naupliar development of an Estherid crustacean; Dr. Grove on sexual congress in earthworms; Miss Breeze on invasion of the tissues of the higher plants by protozoan parasites.

A whole-day trip on the Lancashire and Western Sea Fisheries Committee's steamer, the *James Fletcher*, should be of interest to marine biologists, and a half-day in Delamere Forest should prove attractive to entomologists.

Section E (Geography).

The programme of Section E will open on September 13 with the address of the president, Dr. Vaughan Cornish, who will speak on the geographical position of the British Empire. The remainder of the morning will be occupied by papers explaining the local geography of the Liverpool district. Papers of this nature have been a feature of Section E for some years, and have been appreciated by visitors from a distance. In view of the location of this year's meeting, endeavours have been made to secure contributions dealing with Imperial geography, a question affecting the world-wide interests of Liverpool. Mr. O. H. T. Rishbeth will speak on Australian railway development, Miss B. S. Hosgood will discuss post-War emigration from the British Isles, and Mr. W. H. H. Arden-Wood will contribute a paper on the alluvial lands in India in relation to man and his activities. Other papers include the historical geography of Belgium, by Prof. L. W. Lyde, the Alps of Chinese Tibet, in which Prof. J. W. Gregory will deal with the important results of his recent journey, and the high plateau of Brazil by Mr. R. R. Walls. Rev. W. Weston will give a lantern lecture on the influence of geographical environment on the characteristics of the Japanese, and Prof. J. L. Myres will lecture on the Marmora region. Two joint discussions have been arranged with Section H, on the place of man and his environment in the study of the social sciences, which will be opened by Prof. J. L. Myres; and with Section L, on geography as a basis for a general science course, which will be opened by Sir Richard Gregory. Several excursions of geographical interest have been arranged, and there will be an exhibition of maps of the district prepared by members of the Liverpool Regional Survey Association.

Section G (Engineering).

The subject of the presidential address in this Section is "Transport and its Indebtedness to Science"; a new departure is being made by devoting the remainder of the morning (Friday, September 14) to papers on various branches of the same subject by experts in these several branches; Mr. Berriman, of the Daimler Co., will deal with road transport; Mr. Wall, of Liverpool, with sea transport; Mr. O'Brien, of the L.M. and S. Rly., with rail transport; and Gen. Sir Sefton Brancker with air transport.

On the morning of Thursday, September 13, Section G joins with Sections A and B in a discussion on "Cohesion and Molecular Forces." In the afternoon a joint discussion is being held with the Psychology Section on the subject of "Vocational Tests in the Engineering Trades," to be opened by a paper by Messrs. Fleming and Brocklehurst, of the Metropolitan-Vickers Electric Co.

Monday, September 17, is being devoted mainly to papers on mechanical and general engineering, while most of the papers on electrical engineering will be read on Wednesday, September 19. Tuesday morning begins with a joint discussion with the Education Section, on "The Teaching of Dynamics," opened by Sir J. B. Henderson; the remainder of the morning is to be devoted to the report of the committee on complex stresses, which includes a number of important papers by various members of the committee.

Among the papers to be read on Monday and Wednesday are the following: The conservation and control of our national water resources, by Mr. J. Parry; the recent developments in excavating machinery, by Mr. Barnes, of the Ruston Hornsby Co.; smoke abatement, by Mr. Kershaw; the electric propulsion of ships, by Mr. Clough, of the British Thomson-Houston Co.; and high-power mercury rectifiers, by Mr. Morrison. All these papers deal either with subjects of great importance at the moment or with those on which great advances have recently been made.

Capt. Slee, of the Marconi International Marine Communication Co., will describe the recent developments in the application of wireless telegraphy to shipping; and Mr. Scott-Taggart will read a paper on receiving apparatus for broadcast reception. Prof. W. M. Thornton will read a paper on the mechanism of gas ignition, and will describe a new method of lighting coal mines which greatly reduces the danger of explosion.

Dr. T. F. Wall will describe a new type of induction motor which, although of the squirrel-cage type, has many of the advantages of a slip-ring motor. Prof. Marchant will read two papers, one on a method of improving the wave-shape of an alternator, and the other on the triple-frequency currents which occur in the earth-return of three-phase cables. A paper on water turbines is being read by Dr. H. Mawson, and another on the strength of forked connecting rods by Mr. W. J Kearton.

Section H (Anthropology).

Mr. Percy E. Newberry's presidential address to the Section will be on "Egypt as a Field of Anthropological Research," and will deal with the origins of Egyptian civilisation, showing that its elements are not all native to the soil. Mr. Newberry will also deal *inter alia* with aspects of Egyptian culture in opening a discussion on "The Origin of Domesticated Plants and Animals." A second organised discussion in a joint session with the Geographical Section will deal with "The Place of Man and his Environment in Sociological Studies," to be opened by Prof. J. L. Myres. Sir Arthur Evans will embody, in a consideration of "Crete as a Stepping-stone of Early Culture," some extremely important discoveries recently made by him in that island. Mediterranean archæology will also be represented by two communications from Mr. Stanley Casson on "The North Ægean Coast in the Bronze Age" and "Prehistoric Sites in the Dardanelles and Bosporus."

In British archæology several papers will deal with Welsh prehistory, including a general survey by Prof. H. J. Fleure, and an account of "The Hill-forts in North Wales and their Historical Background," by Dr. R. E. Mortimer Wheeler. Prof. E. Ekwall, of Lund University, will discuss "The Early History of Lancashire in the Light of its Place-names."

In ethnography, Mrs. Scoresby Routledge, in "Mangarevan Folk-lore," will give an account of some results of her recent expedition to the Austral Islands and Mangareva; Mr. E. Torday will describe the methods of native traders in Central Africa, and will give an account of Hungarian folk-music, with instrumental and vocal illustrations. Mr. Torday has also arranged for a band of Hungarian gypsy musicians to perform at an evening soirée. This will give added interest to Dr. John Sampson's paper on "The Origin and Early Migrations of the Gypsies." The Near East will also be represented by Baron F. Nopsca's account of "House-building and House Implements in Northern Albania." Among a number of other interesting communications, space will permit mention only of an account of the culture of the stone-using peoples of Central Celebes by Dr. A. C. Kruyt, who has recently returned from an expedition of scientific investigation in that island.

Section I (Physiology).

The scope of Section I, comprising, as it does, physiology, histology, experimental pathology, experimental biology, and a good deal of biochemistry, is very wide, as the list of papers shows. The presidential address by Prof. G. H. F. Nuttall, on "Symbiosis in Animals and Plants," is a good example of this broad outlook. One of the most attractive items on the programme is a lecture on "Insulin and its value in Medicine," by Prof. J. J. R. Macleod, who has been closely associated with this remarkable discovery of the treatment of diabetes, made in his laboratory in Toronto by Prof. Banting and Dr. Best. On the medical side there are also papers by Dr. S. Monckton Copeman, of the Ministry of Health, on "Diet and Cancer"; by Prof. J. M. Beattie, on "The Action of Finely Divided Particles of Slate, etc., on Toxins"; by Prof. H. E. Roaf and Dr. F. W. Edridge-Green, on colour vision; and by Dr. M. C. Grabham, on "Dental Caries at Porto Santo."

The more academic aspects of physiology are represented by papers by Prof. H. Zwaardemaker of Utrecht, on "Bioradioactivity and Humoral Environment"; Prof. R. Magnus, of Utrecht, on "The Action of Carbon Dioxide and Adrenaline on the Bronchi and Pulmonary Vessels"; Prof. H. E. Roaf, on "The Analytical Mechanism of the Cochlea"; Prof. J. S. Macdonald, and collaborators, on the physiology and energetics of walking; Prof. J. S. Macdonald and Dr. F. A. Duffield, on the physiological cost of cycling; Dr. W. Waller, on the "Red Blood Corpuscles"; and Prof. C. Lovatt Evans, on the "Contraction of Plain Muscle."

The more physical and chemical side will take the form of a discussion, with the Chemistry Section, of "The Physico-Chemical Properties of Membranes in their Relation to Physiological Science," and papers by Dr. S. C. Brooks (representing the American Association) on "The Electrolytic Conductance of Micro-Organisms"; Dr. E. B. R. Prideaux, on "Membrane Potentials"; Mr. T. C. Angus, on "A Recording Katathemometer"; Prof. W. Ramsden, on "Coagulation of Albumin at Free Surfaces"; Prof. W. Ramsden and Mr. J. Brooks, on "Factors determining which of Two Liquids form the Droplets of an Emulsion"; Prof. W. Ramsden, on "Adsorption Films"; Dr. R. Coope and Prof. W. Ramsden, on clinical chemical tests; and Prof. H. E. Roaf, on "The Oxygen Content of Methæmoglobin." Some of these will be of the nature of demonstrations, and histology will be represented by a cytological demonstration by Prof. Charles E. Walker and Miss F. M. Tozer.

Section J (Psychology).

The psychological topics to be discussed this year in Section J are, in the main, similar to those presented last year at Hull. A large number of the papers have a definite and practical bearing on education and industry. Special stress is placed in several papers on the importance of individual differences. This is explicitly so in the presidential address by Mr. C. Burt entitled "The Mental Differences between Individuals—with special reference to Applied Psychology in Education and Industry."

The connexion between psychology and other sciences is again clearly shown by the titles of the joint discussions. With Section F (Economics), "The Inter-connexions between Economics and Psychology in Industry" will be discussed; and an endeavour made to study the psychological factors entering into the economic field. With Section G (Engineering), "Vocational Tests for Engineering Trades" will be described. With Section L (Education), "The Delinquent Child" will be studied—the papers dealing largely with a classification of the commoner delinquencies according to their psychological nature.

A glance at the programme shows that there are two topics of great interest both to education and to industry which receive special treatment, namely, (1) vocational guidance and vocational tests; (2) mental efficiency and fatigue. Important in this connexion will be the results presented by research workers of the National Institute of Industrial Psychology, notably in a paper on "The Conception

of Fatigue," by the director of the Institute, Dr. C. S. Myers.

In addition to the sessional programme, a series of afternoon lectures and lecturettes have been arranged; and a Citizens' Lecture entitled "Skill in Work and Play" will be given by Prof. T. H. Pear.

SECTION K (BOTANY).

This Section will meet under the presidency of Mr. A. G. Tansley, whose address will deal with "The Present Position of Botany." Most branches of botany are well represented in the programme, and, as in recent years, papers of a cognate nature will be grouped together so far as possible. The only joint discussion arranged this year is one on "Virus Diseases of Plants," in which Sections K and M will meet. This discussion will be opened by Dr. Paul Murphy, who will be followed by Prof. H. M. Quanjer, the eminent Dutch investigator of these curious maladies. One morning session will be devoted to morphological problems, including papers by Dr. D. H. Scott and Prof. Lang on the organisation of vascular plants considered in the light of fossil history. Prof. Seward will speak on the Cretaceous floras of Greenland. Plant physiology will again be strongly represented, among others, by Dr. F. F. Blackman on "Oxidation and Respiration," by Prof. Dixon on the "Extraction of Sap by means of Compressed Air," and by Prof. V. H. Blackman and his colleagues on "The Effect of Electric Currents on Plant Growth." A discussion will take place on "The Effect of Soil Sourness on Plants," in which most of the chief British ecologists will take part. There will be a considerable number of papers on cytology and mycology, also communications on floral morphology by Miss Saunders and Prof. J. McLean Thompson. In addition, a large number of papers of a miscellaneous nature will be presented. The popular lecture will be given this year by Dr. W. L. Balls on the appropriate subject of "Cotton."

Several interesting excursions have been arranged, including visits to the West Lancashire sand dunes and to Ingleborough. As in the last few years, opportunity will again be afforded for the display of botanical specimens of special interest in one of the rooms of the Section.

SECTION L (EDUCATIONAL SCIENCE).

The president of the Education Section for the meeting at Liverpool is Dr. T. P. Nunn, principal of the London Day Training College, who is taking as the subject of his address "The Education of The People"; following the examples of his two predecessors, Dr. Nunn wishes the address to be followed by a discussion, and this will be opened by Prof. Campagnac. The first paper on Thursday, September 13, will be read by Prof. O. Jespersen, of Copenhagen, a scholar of wide reputation, upon "Grammar and Logic," and a large audience is expected to hear him. The morning of Monday, September 17, will be devoted to a joint meeting of psychologists and educationists to discuss the subject of "The Delinquent Child." The chair at this meeting will be taken by Mr. C. Burt, psychologist to the London County Council and president of the Psychology Section, who has made a special study of the problem; he will be followed by Dr. Gordon, of Bath, Dr. Potts, and Miss Crossland. This discussion, which arises out of that upon psycho-analysis last year at Hull, is expected to be one of the most popular of the meeting. On the afternoon of the same day, there will be a joint discussion with the Section of Geography on geography as a basis for a general science course. The report of a committee appointed last year upon this subject will be presented.

On Tuesday, September 18, Bishop Welldon, Dean of Durham, will raise the question in a paper as to how far the value of education in elementary schools has corresponded with the increase of expenditure upon it, and it is probable that a very animated discussion will follow the paper.

During the past two years, several Sections have tried the experiment of having semi-popular lectures in the afternoons. The Education Section is following this example at Liverpool, with a paper upon "The Education of Children in Music," by Dr. C. S. Grundy, who will be assisted by a full professional orchestra, kindly arranged by Messrs. Rushworth and Dreaper, of Liverpool. There will also be a paper by Miss Margaret Einert upon "Rhythmic Dancing," illustrated by a demonstration. Each of these papers will be read at 5 o'clock, the former on the Thursday, the latter on the Tuesday afternoon.

Other topics to be considered are education and business life, the older children in elementary schools, literary appreciation in elementary schools, and the teaching of dynamics.

SECTION M (AGRICULTURE).

The meetings of Section M will be held under the presidency of Dr. C. Crowther, principal of the Harper Adams Agricultural College, whose address on "Science and the Agricultural Crisis" will be given in the morning of Thursday, September 13. Two papers from Dr. Stenhouse Williams and his co-workers at the National Dairy Research Institute at Reading will precede the president's address. After the address Mr. Hay will read a paper on agricultural economics and the development of agricultural education.

On Friday, September 14, the work of the Section will begin with two papers on frit-fly problems by Dr. Fryer and Mr. N. Cunliffe, and these will be followed by a joint discussion with Section F (Economics), in which the subject will be "The Economic Outlook for British Agriculture." The speakers in this discussion will include Mr. Forrester and Mr. A. W. Ashby.

On Saturday it is proposed to visit the Lactose Factory at Haslington, and typical cheese-making farms of that area later in the day.

The following Monday morning will be devoted to papers dealing with problems of interest from the side of physical science. The local sectional secretary, Mr. E. Rideout, will speak on the soils of Wirral, and Prof. Sven Oden, of Stockholm, on his apparatus for the mechanical analysis of soils. Different aspects of the soil water and of the soil solution will be dealt with by Mr. E. A. Fisher, of the University of Leeds, and by Prof. Hoagland and Prof. Burd, of the University of California. In the afternoon an excursion will be made to farms of the Wirral peninsula.

The concluding day of the meeting will be devoted to a discussion with Section K (Botany) on the virus diseases of plants, at which the principal speakers will be Dr. Murphy, Dr. Quanjer and Dr. Brierley, followed by a paper by Mr. G. D. Miln, of Messrs. Gartons, on the commercial value of indigenous strains of pasture grasses. Mr. Atkins and Mr. Fenton will discuss the relation of soil acidity to the natural distribution of certain pasture plants. The work of the Section will conclude with a visit to Messrs. Gartons' seed establishment at Warrington, which should form a fitting conclusion to what promises to be a sectional meeting of exceptional interest.

The Hydrogen Molecule.

By Prof. H. STANLEY ALLEN.

MODELS for the representation and elucidation of physical phenomena have played an important part in the advancement of science. Mathematicians, who employ the method known as "the ignoration of co-ordinates," may be satisfied with either a kinetic or a static model for an atom or a molecule, but the physicist and especially the chemist will, as a rule, prefer a static model. Sir J. J. Thomson[1] has done much to bridge the gap between chemistry and physics by making a serious attempt to show how, on the electronic theory of matter, atoms may be linked together to form the stable system which constitutes a molecule. To avoid the difficulties inherent in the view that the electrons are in orbital motion, he is led to postulate a more complicated law of force than that of the inverse square of the distance. For example, he considers the result of assuming a repulsion varying inversely as the cube of the distance superposed on the ordinary electrostatic attraction between a positive charge and an electron. Such a law of force may be adjusted to meet the requirements of the quantum theory. Dr. Irving Langmuir[2] has shown that a model of a static hydrogen atom may be obtained possessing many of the properties of the Bohr atom with its circling electrons, if it be assumed that, in addition to the Coulomb force between charged particles, there exists a "quantum force" given by

$$F = \frac{1}{mr^3}\left(\frac{nh}{2\pi}\right)^2,$$

acting between an electron (mass m, charge e) and a nucleus. In this formula n is an integer, and h is Planck's constant. When the electrostatic attraction, e^2/r^2, between electron and nucleus is balanced by the repulsion due to the "quantum force," the stationary electron is in stable equilibrium at a distance from the nucleus $r = a_n$, where

$$a_n = \frac{1}{me^2}\cdot\left(\frac{nh}{2\pi}\right)^2,$$

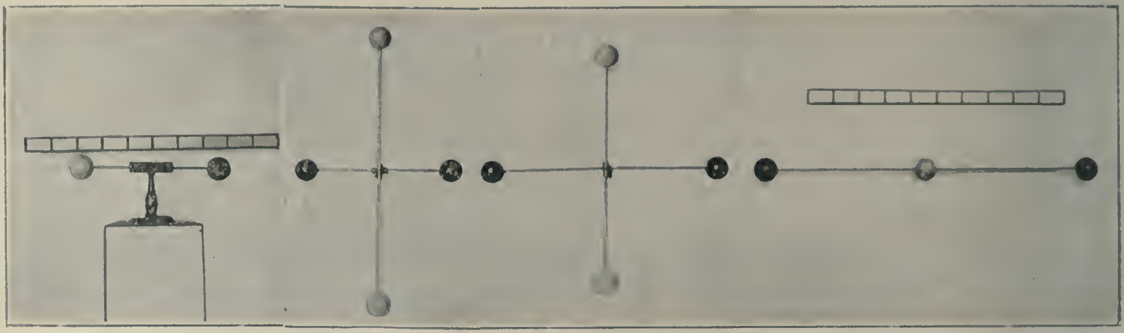
which is the radius of a circular orbit in Bohr's theory of the hydrogen atom. When $n = 1$, we obtain the normal hydrogen atom represented in Fig. 1 (a), in which the black ball stands for the positive nucleus, or "proton," the white ball for the negative electron. The scale above the model represents one Ångström unit, that is, the one hundred millionth part of a centimetre. The distance between the centres of the spheres is 0·531 Å.U., with an error of perhaps one or two units in the third significant figure. No physical meaning is to be attached to the size of the spheres themselves.

In a paper published by the Physical Society of London[3] the writer has pointed out that a force of exactly the type required in Langmuir's theory is provided by the quantum mechanism described by Prof. E. T. Whittaker.[4] Thus a static atom may be obtained by transferring the motion of the electron in Bohr's atom to the rotation of a "magnetic wheel" in the quantum mechanism. The question then suggested itself whether it might not be possible to obtain a static model of the hydrogen molecule by endowing the nucleus or the electron with a magnetic wheel. After considering various possible cases of this kind which gave models not differing greatly in scale from what might be expected on experimental grounds, it appeared that the simplest and probably the most accurate results were obtained by postulating the existence of a "quantum force" of the kind introduced by Langmuir, but exerting repulsion or attraction according to the sign of the electrical charges between which the force acts. It will, then, be assumed that in addition to the electrostatic force, e^2/r^2, between elementary charges, there exists a "quantum force"

$$F = e^2 \cdot \frac{a_n}{r^3},$$

which is repulsive for unlike charges, but attractive for like charges.

Before considering the configurations obtained on this basis, it will be well to recall the model of the hydrogen molecule devised by Prof. Bohr. This is represented in its most stable form in Fig. 1 (b) on the same scale as was employed for the hydrogen atom. The two electrons (white balls) spin round in a circular orbit in a plane bisecting at right angles the line joining the hydrogen nuclei. The electrons, which are always at opposite ends of a diameter of the circle, have each an amount of angular momentum, $nh/2\pi$, determined by Nicholson's quantum condition. It is easy to show that an electron must be at the vertex of an equilateral triangle having as its base the



(a) Hydrogen atom. (b) Hydrogen molecule (Bohr). (c) Hydrogen molecule (static model). (d) Charged hydrogen molecule.

FIG. 1.—Models representing the hydrogen atom and molecule. Black balls represent the positive nuclei and white balls the electrons; scale above the models = 1 Å.U. (0·00000001 cm.).

[1] *Phil. Mag.*, vol. 41, p. 510, 1921.
[2] *Phys. Rev.*, vol. 18, p. 104, 1921.
[3] Proc. Phys. Soc., vol. 34, p. 198, 1922.
[4] Proc. Roy. Soc. Edin., vol. 42, p. 129, 1922.

line joining the nuclei, the length of the base being $1 \cdot 1007 a_n$.

It is generally admitted that while the Bohr atom is able to account quantitatively for the phenomena associated with it, the Bohr molecule is far from satisfactory. If a "quantum force" act between each pair of the four electric charges which constitute the neutral molecule, it is possible to replace Bohr's model of the hydrogen molecule by a model with the electrons at rest relatively to the hydrogen nuclei. Various configurations of equilibrium are theoretically possible, but not all of these are stable. The most stable configuration, from the point of view of ordinary statics, appears to be that in which the nuclei and electrons are situated at the corners of a square, with the nuclei at the ends of one diagonal and the electrons at the ends of the other. The length of a diagonal is $1 \cdot 6407 a_n$. When $n=1$, the length of a diagonal is 0·871 Ångström units, and this case is illustrated in Fig. 1 (*c*). Another configuration agrees exactly with that obtained from Bohr's theory and is shown in Fig. 1 (*b*), but the electrons are now at rest instead of in circular motion. In a third configuration, the positions of the charges are similar but the positions of the black and white balls must be interchanged.

It is possible that such configurations might exist for a time side by side, and such a possibility is suggestive in connexion with the varied values sometimes found in determinations of ionisation potentials. When collisions between gaseous molecules are taken into consideration, it is not easy to say what would be the most probable configuration in the final distribution. It is certainly instructive to find such a possibility of different configurations in the case of the simple hydrogen molecule, and points to the necessity of guarding against too rigid an interpretation of the phrase "gaseous molecule" in speaking of more complex gases, whether elements or compounds.

The actual existence of a positively charged hydrogen molecule is demonstrated in experiments by Sir J. J. Thomson and Dr. Aston. On the present hypothesis a stable configuration is obtained by placing the single electron at the middle point of the line joining the atomic nuclei. In the one-quantum state the distance between the nuclei is 1·239 Å.U., as in Fig. 1 (*d*). The ionisation potential for the complete dissociation of the charged molecule is 17·34 volts as against 11·87 volts on Bohr's theory. This should serve to discriminate between the two theories.

A possible configuration may be suggested for a neutral triatomic hydrogen molecule, H_3, in which the nuclei and electrons are situated at alternate corners of a regular hexagon (length of side, 0·625 Å.U.).

Some of the more important numerical data are collected in the following table; full details will appear in a paper in course of publication in the Proceedings of the Royal Society of Edinburgh.

TABLE I.

	θ.	d_1 (Å.U.).	$I_1 \times 10^{41}$.	W (volts).
Neutral hydrogen molecule	45°	0·871	6·261	30·06
	60°	$0 \cdot 584_5$	2·818	29·68
	30°	1·012	8·453	29·68
Ionised molecule		1·239	12·66	17·34
Triatomic molecule			9·726 19·452	46·25

θ = angle between the line joining nucleus and electron and the line joining nuclei.
d_1 = distance between the nuclei in the one-quantum state.
I_1 = moment of inertia in C.G.S. units for the one-quantum state.
W = work required for complete dissociation expressed in equivalent volts.

The ionisation potentials calculated from the values of W in the table are in moderately good agreement with the experimental results. A more exacting test of the accuracy of such a model is to be expected from a study of the wave-lengths of lines in the secondary spectrum of hydrogen. Even though the numerical values quoted may have to be modified, it may be claimed that it is now possible to postulate a hydrogen molecule in which the electrons are at rest instead of in orbital motion. It is obvious that the principles here employed may be applied to more complex atomic and molecular systems.

The Liverpool Observatory (Bidston).

AFTER a career of eighty years, during which the Liverpool Observatory has fulfilled the purpose for which it was designed, the Mersey Docks and Harbour Board, which is responsible for its support and management, has decided that the time has arrived when the usefulness of the institution might be increased by directing its energies into channels additional to those originally contemplated. It may be recalled that the chief objects sought in establishing an Observatory in Liverpool were the communication of accurate time to the Port and the rating of chronometers. The action of the British Association at the Liverpool meeting in 1837 contributed largely to the adoption of the necessary measures; the meeting in 1923 might give similar encouraging support to the widened programme now under consideration.

The Mersey Docks and Harbour Board considers that the facilities which the Observatory affords for the advancement of knowledge and diffusion of science and learning might be increased if a closer union could be established with the University. As a preliminary measure, it is suggested that the future administration and working of the Observatory may be advantageously entrusted to a joint committee of the Board and University, each nominating five members. This joint committee has now been appointed, the Board's representatives being Mr. C. Livingston, Mr. H. F. Fernie, Col. H. Concanon, the Marine Surveyor and Water Bailiff, the director of the Observatory; and the University nominees, Mr. C. Booth, Prof. Johnstone, Prof. Proudman, and Prof. Wilberforce.

The Dock Board and the University are actuated by a desire to effect an intimate connexion between the recently constituted Tidal Institute, the Observatory, and the department of the Marine Surveyor. The meteorological statistics collected by the Observatory are useful in extending the researches of the Institute in particular directions, while the tidal measurements conducted by the Marine Surveyor afford the necessary means for testing the accuracy of prediction. This closer co-operation has the additional advantage of removing the inconvenience of overlapping.

By utilising the existing establishment as the nucleus of a geophysical observatory, teaching could be combined with research—an extension which is not only feasible but eminently desirable. None of the past activities need be abandoned. The scientific centre would be maintained unimpaired, and its traditions continued. The greater activity exhibited, and the execution of an enlarged programme arranged

to meet modern requirements, should appeal to the intelligence of a progressive community. Meteorology would be followed on extended and more original lines. Magnetic observations, which unfortunately have never formed a part of the Observatory work, would be actively pursued, and the inconvenience occasioned by the want of accurate magnetic constants removed. The attention already given to seismometry could be increased with advantage. Classes are now held in practical surveying and geodesy, and these, at present hampered by want of room and convenience, could be more fittingly accommodated.

There is a difficulty in finding the necessary funds, especially at this juncture, but if a judicious programme is submitted to the attention of those capable of carrying it into execution, the past history of Liverpool leads one to anticipate that even this obstacle will not be found insurmountable.

The Eleventh International Physiological Congress.

NATIONAL congresses of a general scientific character, like the British Association, have been held in various countries for about a century, but international meetings, limited to a particular branch of science, present greater difficulties, and are of more recent date. The disruptive effect of the Franco-Prussian war was long felt, and the meetings of physiologists, started on the initiative of Michael Foster thirty-five years ago, were at first anxiously confined to the smaller countries, like Switzerland and Belgium. In 1898 a Physiological Congress met at Cambridge, but no meeting took place in Germany until that at Heidelberg in 1907. After Vienna in 1910 and Groningen in 1913, Paris was chosen as the next meeting-place, but the regular succession was broken by the War. The Paris congress was indeed held in 1920, but some nations, who have contributed much to physiology, were not represented. As Prof. J. E. Johansson said in an impressive speech at the closing meeting of the congress held at Edinburgh on July 23-27, many will feel grateful to its president, Sir Edward Sharpey Schafer, for the return to an earlier tradition. It was, indeed, the truly international character of the Edinburgh meeting which contributed largely to its success. For successful it certainly was, both as regards scientific interest and personal relationships. Some twenty nationalities were represented, doubtless a record for physiologists and for Scotland, if not for Britain. The membership of 460 exceeded that of the very successful Groningen meeting (if ladies, not engaged in physiological studies, be deducted).

As regards the programme, the customary informal reception was held on the Monday evening, by Sir Edward and Lady Sharpey Schafer, in the Old College of the University. At the opening meeting on Tuesday morning, July 24, addresses of welcome were delivered by Capt. Walter E. Elliot for the Government, by the Rt. Hon. Sir Thomas Hutchison, Lord Provost of the City, and by Sir J. Alfred Ewing, Principal of the University; Prof. J. J. R. Macleod, of Toronto, delivered a lecture on insulin. Then followed a panoramic photograph of the whole congress. The Lord Provost and Lady Hutchison held a largely attended reception in the evening, and two days later the Congress visited the Scottish Zoological Park; for the rest it was occupied with a crowded scientific programme of about 200 communications, which were given concurrently in three lecture rooms, with additional laboratory demonstrations in the afternoons.

The so-called New University Buildings, which mainly constitute the Edinburgh Medical School, were not planned very satisfactorily, and are not entirely up-to-date, but they possess at least one advantage: they form a compact whole round a central quadrangle, and this feature was of great value for a meeting like the present one. The lecture rooms and other resources of several contiguous departments were simultaneously available. An indicator in each lecture theatre, kept continuously up-to-date, announced what papers or experiments were in progress in the other rooms. Occasionally the communications and their polyglot discussion took more than the 15 minutes allotted to each, and not all the 36 chairmen were sufficiently strict, but in the end the programme was completed without serious delay.

In addition to the opening lecture on insulin, by Prof. J. J. R. Macleod, two other addresses were given to the whole congress. Prof. Ch. Richet, of Paris, spoke on "Les voies de la connaissance autres que les voies sensorielles; étude de physiologie expérimentale," and at the closing meeting a paper by Prof. I. P. Pawlow, of Petrograd, on "The Identity of Inhibition, as a Constant Factor in the Waking State, with Hypnosis and Sleep," was read in English by his son, Prof. W. Pawlow. On the conclusion of this paper, describing recent experimental work on conditioned reflexes, the enthusiastic audience rose to its feet to applaud the veteran physiologist, whose participation in the congress was almost prevented by the refusal of a British *visa* on leaving New York. Permission to land at Southampton (instead of Cherbourg) was, however, obtained by wireless telegraphy during the voyage, through the enterprise of an American colleague and fellow-passenger, who communicated with an English physiologist.

At the closing meeting an invitation to meet in America was conveyed by Prof. A. J. Carlson, of Chicago, as president of the American Physiological Society, and an international committee was appointed to consider the possibility of accepting it, and should the economic obstacles prove too great, to select another place for the meeting in 1926.

It is naturally difficult to single out, for individual mention here, a few of the numerous communications, abstracts of which were issued in advance, arranged alphabetically in book form. They will appear later as a supplementary number of the *Quarterly Journal of Experimental Physiology*. On the first afternoon the section dealing with insulin attracted the largest audience; here F. G. Banting and C. H. Best, of Toronto, reported that they had found insulin in normal rabbit's blood, one unit for about 30 c.c. In the vitamin meeting, held at the same time, it was evident that the subject is attracting more and more attention on the continent. K. Hotta, a Japanese investigator working at Frankfort, described how the characteristic convulsions of pigeons, fed on polished rice, may be entirely prevented by feeding with cholesterol. In yet another section W. R. Hess, of Zürich, reported on the plans for founding a station for high altitude research near the terminus of the Jungfrau railway (about 11,500 feet above sea-level). The peculiar advantage of this site is its ready accessibility, as compared with the Mosso laboratory on the Monte Rosa, which can only be reached with difficulty and during a very limited period of the year; 120,000 francs have already been subscribed, and a further sum of 100,000 francs is considered necessary. This Swiss station is not intended

only for biological work, but also for meteorology, climatology, astronomy, etc.

Among the demonstrations, one by A. N. Richards and J. T. Wearn, of Philadelphia, attracted much attention. They showed how to collect glomerular filtrate by insertion of a very fine capillary into Bowman's capsule in the frog. The crowded laboratory must have increased the difficulties of this very delicate operation. Prof. Richards subsequently explained how the minute volume of fluid was analysed by the nephelometric methods of his namesake, the chemist. The filtrate is rich in chlorides which must be re-absorbed in the tubules, and hence a decision is arrived at with regard to rival theories of urinary secretion. Similarly, Bloor's nephelometric phosphorus determination, modified by H. Winterstein, of Rostock, enabled the latter to investigate the phosphorus metabolism of the central nervous system of the frog; the phosphatides here play a considerable part.

H. J. Hamburger and R. Brinkman, of Groningen, claim that the nervous stimulation of the heart sets free substances which influence the contraction of the stomach and gut in the same way as if the nerves of these organs are stimulated electrically; they term this humoral transmission of nervous impulses.

Papers of methodological importance were communicated by A. Kossel, of Heidelberg, who has discovered in the dinitronaphtholsulphonic acid of naphthol yellow a reagent for the quantitative precipitation of arginine and for the isolation of many other bases, and by E. London, of Petrograd, who described a new method for investigating intermediate metabolism, consisting in the introduction of permanent metal cannulæ into deep-seated abdominal blood vessels.

Owing to the circumstance that a conference on the physiological standardisation of drugs met under the auspices of the League of Nations at Edinburgh just before the congress, pharmacology was well represented. At the congress, J. J. Abel and C. A. Rouiller, of Baltimore, described the further purification of the oxytoxic principle of the pituitary, which they have now obtained as a substance which is 1000-1250 times as active as histamine phosphate on the guinea-pig's uterus; the product also possesses powerful pressor and diuretic properties.

W. E. Brown and V. E. Henderson, of Toronto, find that ethylene will produce complete surgical anæsthesia, being more potent and in other ways preferable to nitrous oxide.

During the congress a number of important cinematographic demonstrations were given; perhaps the most interesting was by A. Krogh, of Copenhagen, which showed, under great magnification, the effect of various agents on capillary circulation (this film should prove of immense value in teaching large classes).

In connexion with the congress a Harvey medal, the work of Mr. Pilkington Jackson, the Edinburgh sculptor, was given to every member, and the University of Edinburgh conferred honorary degrees on eight distinguished foreign physiologists who were present, namely, Prof. F. Bottazzi, professor of physiology, University of Naples; Prof. W. Einthoven, professor of physiology, University of Leyden; Prof. W. H. Howell, professor of hygiene, Johns Hopkins University, Baltimore; Prof. J. E. Johansson, professor of physiology, University of Stockholm; Prof. A. Kossel, professor of physiology, University of Heidelberg; Prof. H. H. Meyer, professor of pharmacology, University of Vienna; Prof. I. P. Pawlow, professor of physiology, University of Petrograd; and Prof. Ch. Richet, professor of physiology in the Faculty of Medicine, Paris.

A Seventeenth Century University of London.

EVERY one knows that London was the last great capital city to be provided with a University. The reason for this is not obvious, but the fact remains that after the failure of Sir Thomas Gresham's great aspiration in the seventeenth century, the mere idea of a University seems to have been dropped until it was revived by the Benthamites in the nineteenth century. But not altogether: a solitary enthusiast now and again raised his voice. In 1647 there was a curious proposal launched in a pamphlet, now extremely rare, for remedying this deficiency. The proposal came to nought, like many educational projects, not only, we may surmise, because the country was in the grip of the Civil War, but, as will appear, by reason of certain difficulties inherent in the scheme. The title of the tract, or rather part of the title—for it is a true child of the seventeenth century, when long titles were the vogue—is "Motives grounded upon the Word of God, and upon Honour, Profit, and Pleasure for the present Founding an University in the Metropolis London, . . ." and the author chose to be known as "a True Lover of his Nation, and especially of the said City."

The True Lover is manifestly a Puritan, and his main concern is with the shortness in the supply of preachers of whom he estimates that we want more than 20,000, "and are hopeless of supply, without other provision than yet we have." The old universities, even at their prime, could not bring forth such numbers. Now was the golden opportunity for London to remedy this lamentable defect "when so many great houses may be had and made Colleges of, with so little alteration, and Pauls Church and London-House be the publike Schooles." Teachers were to be had on as easy terms as buildings: "by reason of the Warres in other Countries, you may now have the choicest of their Professours of the Arts."

But the True Lover's financial plan displays greater optimism than knowledge of human nature warrants. If every sincere Christian in London gave up one meat meal a week it would be possible to maintain, he thinks, twenty thousand "poore Schollars," and a similar abstention throughout the Kingdom an hundred thousand. This greater number by no means dismays the True Lover; on the contrary, it stirs his enthusiasm. After a general course of military training, twenty thousand of the "choycest" would be selected as ministers, the remainder being "imployed in Trades, or Navigation and show themselves for the defence of this country Lions on the Land, and Dolphines on the Seas." The elect would also "Discipline their Parishes and put all England in Israels posture so that we might be a Nation of Souldiers and defend our Religion both with Divine arguments and (if need required) with corporall Armes also."

If the True Lover had read Milton's famous Tractate on Education, published three years earlier, he had not been impressed by it, nor had he apparently breathed any of the ideas which were a few years later to bring about the first meetings of the nascent Royal Society. His notions of curricula may be described as humanistic, coloured with a pronounced utilitarianism. Three colleges were to house the hundred thousand. In one nothing but Latin was to be spoken, and in two years the scholars would thus be able to speak as good Latin as they do English. "How easily afterwards," he exclaims, "would they

attaine the Italian, French and Spanish Tongues, and in Merchandizing be fit to negotiate with the greatest Princes." In a second College nothing would be spoken but Greek, and in a third Hebrew. This would attract all " forraigne Protestants of work in this westerne World," as well as the Jews " whose conversion is now at hand."

The vision of a truly Puritan Paradise opens up. " If London were an University, such, pluming the Crest of this Royall City, would cause it to present a more glorious aspect than all the lofty Cypresses in Constantinople doe unto all that approach unto it: yea, all the yeare long cause London to resemble Jerusalem in the Feast of Tabernacles." Not only would there be a chaplain in every house of the nobility (and even " the Citizens carry one sometimes "), but every godly merchant might have a graduate in his ship, and " Sea-men (generally so prophane) " might become Saints and " their masters goods prosper in their hands."

That there will be objections from Cambridge and Oxford (the order of precedence is his and prompts a conjecture as to the True Lover's upbringing) is foreseen, but these, it can well be imagined, do not daunt such a buoyant optimism. Your True Lover, if he is worthy of the name, has as little difficulty with objections as with finance. Thus there are nine answers to the three objections (" weak, weaker, weakest "), not any of which are objections founded upon such base things as accommodation and finance. Perhaps, however, it was this sort of objection which prevailed with the Lord Mayor and his colleagues (to whom " Motives " are presented), and, as we know, the True Lover's University did not build Jerusalem in London. Which, perhaps, is just as well.

E. D.

Immigration and Degeneracy in the United States.[1]

THE United States Government is taking measures to control immigration, so as to ensure, so far as is possible, that undesirables of all sorts shall be excluded. The present publication, which is the statement of Dr. Harry H. Laughlin made before the Committee on Immigration and Naturalisation of the House of Representatives, is witness to its activity in this direction. By estimating the actual and predicted proportions of various sorts of degeneracy contributed by the various stocks that enter the United States, it is possible, by excluding immigrants from those foreign countries that contribute more than their share, to ensure that the healthiest possible stocks only are admitted.

The statement of Dr. Laughlin covers feeble-mindedness, insanity, criminality, epilepsy, inebriacy, leprosy, tuberculosis, blindness, deafness, deformation, and dependency. It is found that each of these forms of degeneracy demand distinct methods of treatment. For example, it is comparatively easy to control feeble-mindedness, for it manifests itself early in life. Therefore it is found that the native white population contributes, proportionally, more than the immigrant white to the feeble-minded part of the population. On the other hand, insanity, which manifests itself much later in life, is not so easy to diagnose in the immigrant, with the consequence that the immigrants of the present generation have a higher incidence of mental instability than is possessed by the foundation families. Therefore it is proposed that immigrants should come of families with no record of insanity.

The case of crime is interesting. Those countries that have contributed least to the criminal population of the United States are Great Britain, Scandinavia, Ireland, Germany, and the Netherlands; *i.e.* precisely those that have contributed the foundation stocks. The Southern European countries have contributed a far larger proportion, and this is probably due, in the opinion of Dr. Laughlin, to a change in social environment, with a consequent social maladjustment. Since criminalistic tendencies show themselves early in life, it has been possible to exclude this type with a considerable degree of success.

The analysis of figures has made it possible to reach some interesting conclusions with regard to the contributions to degeneracy made by the different constituent elements of the population of the United States, and it is evident from this report that before long we shall know much more than we do at present about the problem of degeneracy. One definite conclusion seems to have been reached by Dr. Laughlin; he states that " custodial inadequates are for the most part recruited from a relatively small portion of the families of the whole population. This means that social inadequacy is not a result of accident or bad environment, but that primarily most custodial inadequacy is founded upon degenerate inheritance."

The ultimate effects of the prosecution of a thoroughgoing policy of immigration control will be far-reaching; for the United States will be able to absorb the healthy stocks, and to reject the unhealthy, thus greatly benefiting itself at the double expense of European countries.

W. J. PERRY.

[1] Analysis of America's Modern Melting Pot: Hearings before the Committee on Immigration and Naturalisation, House of Representatives, Sixty-seventh Congress, Third Session, November 21, 1922. Statement by Harry H. Laughlin. (Serial 7-C.) Pp. 723-831. (Washington: Government Printing Office, 1923).

Fire Hazards and Fire Extinction on Oilfields.

THE subject of fire-risk, prevention and extinction on oilfields is one which the public as a whole tends to take very much for granted, only being stirred to interest by press reports of oil-well fires such as occurred in Trinidad some two years ago, when thousands of pounds' worth of damage was done, or by more serious disasters on some of the American fields, involving the loss of many lives. On the other hand, those concerned with the actual control of oilfields, if not the employees themselves, are very much alive to the ever-present danger of a conflagration arising from the high degree of inflammability of petroleum and its products, and they know, usually only too well from experience, that oil-fires, from the inherent nature of the materials involved, are by far the most difficult to combat successfully.

Prof. J. S. S. Brame chose this subject as the theme of his valedictory address to the Institution of Petroleum Technologists recently, and in view of the rapid and generally unappreciated evolution of modern methods of oil-fire extinction, especially as practised in America, his dissertation was particularly welcome. It certainly stimulated members of his audience to a keener perception of the risks run by those engaged in all branches of the industry, without in any sense being either sensational or alarming.

As with other undesirable evils, prevention being better than cure, the greatest possible care is taken nowadays to meet, by precautionary measures, the contingencies of oil-well and oil-tank fires. Unfortunately, one of the chief causes, lightning, is extremely

difficult to safeguard against, and the loss of oil by ignition of the associated gases during storms is a formidable problem, especially in certain parts of the United States. In the Mid-Continent field, for example, as much as 1,000,000 barrels of oil per annum has been lost in this way.

Preventive measures consist for the most part in the employment of specially designed storage tanks, the wooden top surmounting the metal body being a favoured form in America. This type of tank is open to the objection that continuity of metal is broken, so that perfect protection from lightning cannot be assured. In this country, all-metal tanks are preferred; sometimes steam-lines are led to the tops of the tanks for discharging steam freely at the approach of a thunderstorm, though in the case of large tank-farms the method proves impracticable. Tanks are usually built in the centre of sump-holes, while a clearance of 200 feet between the site of each tank is desirable. Probably the most recent method for preventing oil-tank fires is that concerned with the use of "Sealite," an artificial preparation consisting of a mixture of glucose, glycerin, calcium chloride, glue and starch. This mixture can be rendered lighter than oil by aeration, and when pumped into the tanks it floats on the oil, thus preventing evaporation and also combustion. The better-known "Foamite-Firefoam" system of fire-extinction is only applicable once a fire has started; this depends on the foaming reaction set up by bringing together alum and licorice, by which carbon dioxide is generated, thus effectively choking the fire.

Oilfield fire may of course be due to other causes besides lightning; the friction of the crown-pulley when bailing operations are in progress on the rig; crossed guy-lines or wires causing sparks which ignite the volatile gases; the throwing down of lighted cigarette-ends (regarded as a criminal offence in some countries—and rightly so); spontaneous combustion of gas-lines; leaky pipe-lines; all these contribute to the possible risks to be guarded against.

A somewhat novel and generally unsuspected cause of petrol-fires is the power which the mobile spirit has of generating static electricity. Ignition of volatile oils through static discharge has been known in hairdressers' shops, in garages where men have chanced to clean their hands with silk rag soaked in petrol, in filling up petrol tanks of motor cars using a piece of chamois leather for filtration purposes. A still more curious case is that of the chauffeur who was drawing from a self-measuring tank into a can bearing a wooden handle; he hung the can by this handle, thus insulating the receptacle, and under these conditions the oil caught fire on two successive occasions.

The moral of these examples is obvious. They serve to show, however, the meticulous care necessary in handling petroleum under all conditions, and it speaks volumes for the administrative and technical ability of those responsible for storage and distribution of oils, that the disasters attending oil-fires are so few, not only in Great Britain but also in America, where such vast quantities of inflammable spirit are dealt with annually.

H. B. Milner.

The Greenwich Magnetic Observatory.

Proposed Removal to Holmbury Hill.

Magnetic observations were commenced at the Royal Observatory, Greenwich, in the year 1840. They included absolute observations of the magnetic elements together with eye-observations, obtained at first every two hours and afterwards every hour, for determination of the variation of the elements. In 1847, continuous photographic records of the elements were introduced and have been continued until the present time. The length of this continuous series of observations provides valuable material for the study of the phenomena of terrestrial magnetism. It was by their means that Mr. Ellis demonstrated the 11-year periodicity common to the variations in the diurnal ranges of the magnetic elements and to the sun-spot period, and that Mr. Maunder established the connexion between the recurrence of magnetic storms and the rotation of the sun. More recently, Dr. Chapman, by using the Greenwich observations, combined with similar records of one or two other observatories which have a long series, has been enabled to put forward a comprehensive theory connecting magnetic storms and the regular diurnal variations of the elements with the electrification of and movements in the atmosphere, caused by the discharge from the sun of electrified corpuscles. The Admiralty magnetic charts are constructed at Greenwich, the last issue in 1922 consisting of three large-scale maps showing the magnetic variation, and three smaller maps showing the magnetic variation, dip, and horizontal intensity for the whole world.

During the last twenty years the magnetic observations have all been transferred to buildings constructed of non-magnetic materials in a special enclosure in Greenwich Park away from the iron in the Observatory. The instruments have also been modified and improved. With the growth of electric traction in the latter part of the last century, steps had to be taken to safeguard the Observatory from disturbances due to leakage currents. Since 1903, a protective clause has been inserted in all Parliamentary Bills for electric rail- or tramways running within five miles of Greenwich, and a clause requiring insulated returns if running within three miles. With these safeguards, the disturbances, though perceptible, have been kept within reasonable limits.

On the decision of the South Eastern and Chatham Railway Co. to electrify its local services which run in the near vicinity of, and on both sides of, the Observatory, the question of safeguarding the interests of the Observatory was taken up with the Ministry of Transport. It was ultimately agreed that the most satisfactory arrangement for both parties, and the cheapest for the railway company, would be to move the magnetic observatory to another site, the railway company defraying the costs of the removal and the extra cost of maintenance thereby involved. A site near London was desirable, not only so that supervision from Greenwich would be easy, but also in order to maintain a first-class magnetic station in the south-east of England. After examination of all sites within fifty miles of Greenwich which were at least three miles from any existing railway, the region which seemed to offer least probability of being affected in the future by railway extensions or building operations was that around Holmbury St. Mary in Surrey. The site finally chosen as the most suitable in the neighbourhood is on the lower slopes of Holmbury Hill.

Some opposition has been aroused owing to it being common land. The buildings to be erected on it would be low and not unsightly, and would not interfere with the amenities of the district. The fact of being on common land would, on the other hand,

afford a guarantee against disturbance by possible future building operations. The Admiralty has undertaken to meet the wishes of the Commons and Footpaths Preservation Society by acquiring an equal area of land adjacent to the common and adding it to the common so that the total area of the common will not be reduced.

Academic Biology.

UNDER the title "The Dry-rot of our Academic Biology," Prof. W. M. Wheeler delivered a most provocative address to the American Society of Naturalists, which is printed in *Science* (vol. 57, pp. 61-70). The address may have been written under the reaction from the author's labours upon a volume of 1100 pages upon ants, but it provides food for thought for the teacher of biology. The title seems to have been chosen in part with an impish desire to lead the librarian astray, so that future students of the fungi may find it "reposing unashamed between such monuments of cryptogamic erudition as the 74 folio volumes of Professor Farlow's 'Toadstools of God's Footstool' and the 27 quarto volumes of Professor Thaxter's 'Laboulbeniales of the Universe'"; in part to indicate Prof. Wheeler's foreboding as to the devastating effect of academic biology upon the young minds exposed to the danger.

Apparently 25 per cent. of the young men and women graduating in the United States have had at least the equivalent of an elementary course in botany or zoology, but of these very few exhibit a vital and abiding interest in biological inquiry. This seems to have led to this interesting analysis of the relative ineffectiveness of biological teaching (tinged, perhaps, with the after effects of eleven hundred pages upon ants!). Some of the suggested defects will certainly provoke sympathetic response in Great Britain, for instance the complaint that biologists are compelled to be most active pedagogically during the annual "glacial period," with a consequent reliance upon preserved material of convenient types and a great restriction of field studies. The mature student who, after four years in a divinity school, relinquished attendance upon a course in genetics because the professor's mental processes were so similar to those of his divinity teachers when they held forth on predestination, salvation through grace, etc., is cited as part of a general indictment which suggests the reflection that the best culture medium for the academic dry-rot fungus consists of about equal parts of narrow, unsympathetic specialisation, and normal or precocious senile abstraction. There are redeeming features, however, and the author rejects a friend's remedial proposal that staffs should be completely changed and buildings burnt out or thoroughly disinfected every 25 years! Another tendency which is deplored is the migration of the American graduate to the German laboratory and the teaching of authority, instead of spending the few precious post-graduate years among the problems provided at her door by the flora and fauna of the tropics.

Two positive suggestions for improvement are made: first, that teaching should be more ecological in a very wide sense of the term, and botany is certainly moving very rapidly in this direction in Great Britain; secondly, that opportunities should be provided for the amateur naturalist to meet the young student both in the laboratory and in the field, and so counteract the paralysing influence of academic formalism by his unprofessional enthusiasm and interest.

University and Educational Intelligence.

LONDON.—The work of the Ramsay Memorial Department of Chemical Engineering at University College will begin in October. The department has been instituted with the object of enabling young graduates in chemistry and engineering, who have already obtained a good training in the fundamental sciences of chemistry, physics, and mathematics, to direct their studies and investigations towards the application of the principles of physical chemistry to the scientific design and operation of the apparatus and processes of chemical industry in general. Mr. E. C. Williams, of the University of Manchester, has been appointed professor in charge of the department. An assistant lecturer, who must have had an engineering training, will shortly be appointed by University College Committee.

THE Folland scholarship in metallurgy, in connexion with the University College of Swansea, is to be offered in competition on September 10 and following days. The scholarship is of the annual value of 50*l*., and tenable for three years. Further particulars are obtainable from the Registrar of the College.

A LIMITED number of grants in aid to junior assistants in chemical works and laboratories in or near London, desirous of extending their knowledge of chemistry, will shortly be allocated by the committee of the Salters' Institute of Industrial Chemistry. Applications must be sent before September 15 to the director of the Institute, Salters' Hall, St. Swithin's Lane, E.C.4.

APPLICATIONS are invited by the Royal College of Physicians of Edinburgh for the Parkin prize, value 100*l*., which is open to competitors of all nations, for the best essay on "the curative effects of carbonic acid gas or other forms of carbon in cholera, for different forms of fever and other diseases." Competing essays, which must be written in English, must reach the Secretary of the College not later than December 31 next, bear a motto, and be accompanied by a sealed envelope bearing the same motto outside, and the author's name inside. It is stipulated that the successful candidate shall publish his essay at his own expense, and present a printed copy of it to the college within the space of three months after the adjudication of the prize.

MUCH of the scientific information latent in government publications fails to reach those to whom it would be of the greatest utility. An example of how such information can be made more generally accessible is the index issued by the United States Bureau of Education to documents having a bearing on the subject of home economics. This (revised March, 1923) includes not only 55 of the Bureau's own pamphlets, but several hundreds of others issued by the Department of Agriculture, the Bureaus of Standards, of Mines, and of Fisheries, the Labour Department Children's Bureau, the Public Health Service, the Federal Board of Vocational Education, and the American Red Cross.

"THE janitor of a modern school building is, next to the principal, perhaps the most important officer in the school." This pronouncement by Dr. Dresslar, an American authority on school hygiene, is quoted with approval by the author of "The School Janitor: a study of the functions and administration of school janitor service," Bulletin, 1922, No. 24 of the United States Bureau of Education. The writer goes on to show that although the average annual salary of school janitors is 980 dollars, or more than 50 per cent.

higher than that of elementary and high-school teachers, including principals, most people fail to realise the importance of this service or, indeed, to give the subject any thought at all, with the result that most janitors are selected and appointed for personal or political reasons rather than on the basis of merit, and many are incompetent and physically, mentally, and morally unfit. In view of the large control exercised by them over health conditions, especially as regards cleanliness, air, and light, their moral influence, and the high importance of their work educationally as setting standards of housekeeping and taste, and financially as affecting the preservation of valuable property, it is surprising that this is the first comprehensive study of the subject that has been published in America.

THE teaching of civics and the encouragement of activities making for good citizenship have received a large and increasing amount of attention in the United States since the War. Numerous pamphlets and leaflets issued by the Bureau of Education on "lessons in civics in the elementary grades," "preparation of teachers of the social studies for secondary schools," boy-scouts and girl-scouts, "lessons in community and national life," "Americanisation," "the teaching of civics as an agency for community interest and citizenship" (by the Commissioner of Education), etc., have recorded and stimulated the movement. The last of the series is Bulletin, 1922, No. 45 on "Status of certain social studies in high schools." This gives the results of an investigation conducted by the Bureau in 1922, and compares them with the facts revealed by a similar inquiry in 1919. Important changes have developed in the treatment of civics and economics in the schools, the tendency being to make the courses more practical and to deal with modern social and economical problems instead of merely with the machinery of government and economic theory. Of the 13,000 largest high schools of the country to which a questionnaire was sent in 1922, half sent replies, and of these 88 per cent. offer instruction in civics, most of the courses being obligatory, and 41 per cent. offer courses in economics, more than one-third of which are obligatory.

SOME recent developments in educational journalism are described by Prof. Carson Ryan of Swarthmore College, in Bulletin 25 of 1923 of the United States Bureau of Education. The technical educational journals have been hard hit by the rise in costs of production and have with difficulty held their own. Of the 144 journals listed in the bulletin not more than 10, with an aggregate circulation of less than 40,000, attempt to deal with educational problems in a national way free of associational connexions. Forty-eight State and associational periodicals have an aggregate circulation of 234,800. They include the Journal of the National Education Association, which in less than two years has attained a circulation of 130,000. Educational journalism in the daily newspapers has maintained itself effectively and improved in quality. Although the daily "school page" is still maintained by about 10 per cent. of the chief American dailies, the present tendency in newspaper treatment of education is away from such departmental methods: "educational" news should, it is considered, not be so labelled and should compete with other news for position. On the part of school and college authorities there is a marked disposition to welcome and co-operate with newspaper men. For example, one reporter was allowed to go through the schools of the city, sitting each day in a class-room among the pupils, to write a day-by-day first-hand account of schooling in all the grades.

Societies and Academies.

PARIS.

Academy of Sciences, July 30.—M. Guillaume Bigourdan in the chair.—Gabriel **Bertrand** and B. **Benzon**. A kind of physiological mutation observed in mice. During the study of the effects of the addition of a trace of zinc to the food of mice in the absence of vitamins, one mouse survived eleven weeks before showing any symptom of trouble, while all the other animals lived only from three to five weeks.—V. **Grignard** and M. **Dubien**: The condensing action of the mixed magnesium alcoholates, ROMgX. The alcoholates of the type $C_2H_5 . O . MgI$ produce energetic condensation of aldehydes and ketones, aldols being formed.—Jean **Chazy**. The field of gravitation of two fixed masses in the theory of relativity.—Th. **Varopoulos**: The number of exceptional values of multiform functions.—Ch. **Maurain, A. Toussaint,** and R. **Pris**: The measurement of air resistance on railway material. An account of the results of experiments carried out on a model train, one-twentieth real size.—Albert **Portevin** and François **Le Chatelier**: Obtaining, by heat treatment, light aluminium alloys of high tensile strength not containing magnesium. The effect of the temperature of tempering is given for an aluminium alloy (4·3 per cent. copper, 0·8 per cent. manganese, 0·38 per cent. silicon) and the results contrasted with alloys of the duralumin type containing magnesium.—André **Job** and Guy **Emschwiller**: The photochemical reduction of zinc sulphide. Phosphorescent zinc sulphide suspended in air-free water and submitted to ultraviolet radiation from a mercury lamp gives metallic zinc and free sulphur, some centigrams of zinc per hour being formed.—MM. **Wertenstein** and **Jedrzejewski**: The evaporation of carbon. The rate of evaporation (m) of carbon filament has been determined at temperatures between 2800° and 3500° C. absolute, and the results are in accord with the equation

$$\log m = 14.19 - \frac{47{,}000}{T} - 1.25 \log T.$$

From this, 5100° C. abs. is deduced as the boiling point of carbon.—P. **Lebeau**: A method of thermal fractionation of gases arising from the carbonisation of solid combustibles. The fuel is heated in a vacuum to temperatures increasing by steps of 100° C., and the gas pumped out at each stage and analysed. The results with seven fuels of different type are given in a diagram.—René **Reich**: New organometallic compounds: copper phenyl and silver phenyl. Copper phenyl has been isolated as the result of the reaction of dry cuprous iodide on an ethereal solution of phenylmagnesium bromide (in an atmosphere of nitrogen). The product is unstable, giving copper and diphenyl at 80° C. Copper ethyl proved too unstable to isolate, although there were indications of its formation. Silver phenyl was prepared by a similar reaction; under ether, at −18° C., it is completely decomposed in a few hours into silver and diphenyl.—L. **Bert**: Bromodiphenylmethane and the Grignard reaction. The main product of the reaction of magnesium on bromodiphenylmethane is tetraphenylethane.—M. **Pastureau** and H. **Bernard**: A new method of passing from mesityl oxide to tetramethylglycerol.—Alphonse **Mailhe**: The preparation of petrol starting with animal and vegetable oils. Rape oil, heated with zinc chloride, has been shown in an earlier communication to give rise to low boiling hydrocarbons. It is now shown that various other animal and vegetable oils behave similarly on heating anhydrous zinc chloride.—R. **Fosse**, Ph.

Hagène, and R. Dubois: Xanthyl compounds derived from amino acids.—Albert Michel-Lévy and Henri Termier: The Trapp rocks in the region of Raon-l'Etape (Vosges).—Etienne Patte: The isle of ashes, an Indo-Chinese volcano of recent appearance. This volcanic island was discovered in the process of formation by the Japanese ship *Wakasamaru* on March 2, 1923. The volcano was very active a fortnight later. By May 27, the area of the island had been reduced by about one-third, and the eruption had ceased.—F. Ehrmann and J. Savornin: Complement to the stratigraphic scale of the Kabylie des Babors, Algeria.—G. Pontier: The fossil elephants of England. The mutations of *Elephas antiquus* in the upper Pliocene and English Quarternary.—H. Colin and H. Belval: The soluble hydrocarbons of the wheat grain in the course of development.—A. Policard and G. Mangenot: The state of the oil in the reserve cell of the fatty seeds. The seed in germination.—E. Grynfeltt: The anatomical constitution and the signification of the pavilion of the uterine tube in woman.—Jules Amar: The phenomena of respiration. From a consideration of the total surface of the red blood corpuscles and the volume of oxygen consumed per minute, it is concluded that the hæmatic absorption is subordinate to the preliminary solution of the oxygen in the blood fluid. The true function of the red corpuscles is to increase, by their oxygen absorption, and to regularise, like a flywheel, the oxygen reserve of the higher animals.—R. Faillie and J. P. Langlois. The energy expenditure of the organism in walking down hill on an inclined plane.—R. Herpin: The swarming in full daylight of a *Pionosyllis lamelligera*.—Emile F. Terroine and H. Barthélémy. The composition of the organisms in the course of ovogenesis in the frog, *Rana fusca*. There is not a synthesis of fat at the expense of the tissues, but a transport to the ovary of fat previously accumulated in the organism. At the moment the eggs are delivered, the animal, without the ovaries, contains a very small proportion of fatty matter.—Ch. Dejean: The origin of the vitreous body and of the zonule.—O. Duboscq and P. Grassé: The small flagellæ of *Calotermes flavicollis*.—Etienne and Edmond Sergent and A. Catanei: Vaccination against paludism of birds obtained by the inoculation of a small number of living sporozoites.

MELBOURNE.

Royal Society of Victoria, June 7.—E. J. Hartung: The Mount Wilson solar observatory. A general account of the spectroheliograph and the establishment of the observatory on Mount Wilson was given. The solar tower telescopes, and the great reflectors for stellar and nebular work, were described and some of the lines of investigation which these instruments have rendered possible, were discussed. In conclusion reference was made to the projected Australian solar observatory on Mt. Stromlo, from which much may be expected.

June 14.—Mr. Wisewould, president, in the chair.—E. F. J. Love: Acceleration of gravity at the Melbourne Observatory. On taking Wright's determination into account, together with those utilised by the author in his previous paper, the value of g is increased, and the mean error diminished by 0·001 cm./sec.$^{-2}$. Reasons are given for regarding Wright's recent suggestion of variation in g with the time as unnecessary.—Sydney Pern: Different types of Australian boomerangs and their flight. The different types of war and return boomerangs, found amongst the various tribes were described, and also the methods of making the boomerangs, and how they were thrown. The author attributed the origin of the boomerang to the slow evolution of the throwing stick, which, when flattened and slightly twisted, was capable of greatly increased range. This stick took a slightly circular course, and by modifying it, a boomerang which would return was eventually developed. The different flights possible with the return boomerang were illustrated by wire models, and the method of throwing them to attain these different flights were explained. Four different ways of making the return boomerang were shown.

SYDNEY.

Linnean Society of New South Wales, April 18.—Mr. A. F. Basset Hull, president, in the chair.—W. F. Blakely: The Loranthaceæ of Australia, Pt iv. A continuation of the systematic descriptions, eleven species and six varieties being dealt with, of which six species and five varieties are described as new.—H. I. Jensen: Some notes on the Permo-Carboniferous and overlying systems in Central Queensland. A summary of the results of geological reconnaissance work in the country lying between the Charleville Railway line and the Longreach Railway line in Western Queensland. Notes are given on the geological sequence in the Carnarvons and on the Bowen formations in the type district.—Vera Irwin-Smith: Studies in life-histories of Australian Diptera Brachycera. (i.) Stratiomyiidæ. No. 4. The respiratory system in larva, pupa and imago of *Metoponia rubriceps* Macquart. A contribution to the subject of the post-embryonic development and comparative morphology of the respiratory system in Diptera and in insects in general.

May 30.—Mr. A. F. Basset Hull, president, in the chair.—H. J. Carter: Revision of the genera Ethon, Cisseis, and their allies.—T. Harvey Johnston and G. H. Hardy: A revision of the Australian Diptera belonging to the genus Sarcophaga. This group of flies is of medical and veterinary interest. Eight names are placed as synonyms for the first time, one new species is described, one is given a new name, and one, which evidently has been imported from North America, is added to the list, making twenty-three species now known from Australia.—A. A. Lawson: The life-history of *Microcachrys tetragona* (Hook.). Practically a complete account of the gametophyte structures of one of the rarest and most interesting of the Australian Podocarpineæ.—J. McLuckie: Studies in symbiosis. iv. The root-nodules of *Casuarina Cunninghamiana* and their physiological significance.

Inventors and Patents.

THE relations which exist between an employer and his employee as regards patents for inventions are well known and, on the whole, are just and stand the test of time. On our part, we are always ready, and indeed anxious, to uphold the rights of inventors ; none the less so when the inventor happens also to be an employee. That there have been acts of injustice towards the employee is notorious, and that an inventor occasionally suffers at the hands of his employer is beyond dispute. It is well, therefore, to be reminded from time to time of the employee's views, if only to seek opportunity for the removal of hardship under which the employee-inventor may labour. To his grievances a short article by Mr. P. Freedman is devoted in the July-August number of the *Scientific Worker*, where, by a series of selected examples, there is advanced "a rough but true picture of the present trials of the needy inventor who is an employee of a private firm."

The details, however, of these examples, whereby the conclusions which have been drawn from them may be checked, are wholly absent. But without impugning in any way the accuracy of the examples, considerable experience suggests that the addition which inventors make to the stock of public knowledge is often neither so great in amount nor so important in extent as inventors would have us believe. Many a brilliant idea proves to be almost valueless to the community unless means for presenting it in practical form are devised by those whose everyday business is the immediate satisfaction of the public wants. Employers, as is said, must live, and it is to their interest to adopt the latest and most efficient devices irrespective of the quarters in which they arise. The subtle and elusive quality of inventiveness is such as to require all the efforts of employers to stimulate its exhibition by those in their employ. Harsh and inequitable treatment of employees conduces to the satisfaction of neither party. In short, mutuality in aim with due regard to the dictates of justice are, in the long run, found to pay.

In the same article the suggestion is put forward for a patents committee to be set up to report upon novel ideas, the members of the committee being thoroughly able technical men and men of high reputation. The good opinion of this body would enable the inventor "to obtain financial backing for his idea and free him from rank robbery." It would also help, it is said, in bringing the inventor into touch with those who might assist him in furthering his aims. The author of the article deliberately abstains from elaborating the scheme in detail, but in this matter urges energetic action

as the policy of the National Union of Scientific Workers.

The idea of a patents committee of this character, it may be remarked, is a favourite one with reformers, but however much there is to be said in its favour, its formation, functions, and operations would be such as to render the idea all but impossible in practice. A very near approach to the constitution and working of such a committee was to be witnessed during the War. Many consultative bodies, in the exceptional circumstances of the time, were established by the Ministry of Munitions for estimating the value of inventions. As a result, a vast accumulation of information upon the practical working of those consultative bodies was obtained; information which, if made available to the public, would indicate how little the expectation of reformers in this direction could be realised. Sound contribution to the discussion of the relation between employer and employed as regards inventions and their mutuality of interest is ever welcome, and in the proper quarters should always receive careful attention. It is open to question, however, whether the claims of the employee will be materially enhanced by the advocacy which appears in the *Scientific Worker*, where some basic misconception occurs in respect of the employee's legal position, and where the implication lies that all employers are to be judged by reference to the action of those who abuse their position.

In a second article devoted to patents in the same issue of the *Scientific Worker* Dr. N. R. Campbell urges the entire abolition of the patent system without any definite substitute. He considers that the system gives industrialists a wholly false view of the place of science in industry and, in consequence, diminishes the number of scientific workers whom they employ. "So long," says Dr. Campbell, "as we associate scientific work with patents, the delusion that is responsible for the backward state of scientific industry in this country will continue," and, if patents were abolished, manufacturers would have to rely upon the excellence of their products and the efficiency of their processes and not on the establishment of monopolies. There must be dismissed once for all, Dr. Campbell continues, the wild idea that, by some modification of patent law or machinery, there can be wrested from the greedy capitalist some enormous profit that he makes by exploitation of the inventor.

Dr. Campbell refers also to the necessity, in the case of a really important invention, of spending many thousands of pounds upon defending a patent in the courts. This necessity is and has been a crying evil which seems to be almost inseparable from the existing patent law. It is indeed remarkable that the talent of the legal expert united with the genius of the manufacturer have not yet succeeded in evolving a scheme whereby, at a relatively small cost, the scope of an invention may be accurately defined and the validity of its protecting patent readily determined. The difficulties in the production of such a scheme, which without losing sight of the interests of the public shall yet reserve to the inventor all the rights to which he is entitled, are undoubtedly great; but surely some means are discoverable whereby the present outlay for obtaining confirmation of an important patent and the settlement of the allegation of infringement could be much reduced. The National Union of Scientific Workers would indeed be doing true yeoman's service if, in all its bearings, the Union would consider this matter and assist in bringing about a much-needed reform.

The Social Influence of the Internal Combustion Engine.

The Internal Combustion Engine. By Harry R. Ricardo. Vol. 2: *High-speed Engines.* Pp. vii + 373. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1923.) 30*s.* net.

IT does not seem long ago, though actually fourteen years have passed, since we overheard a well-known man of letters gently curb the impulsive pen of a younger writer who wished to record an impression that the increasing use of the internal combustion engine must prove a vital factor in our coming civilisation. Events have moved so rapidly that it now seems surprising that this impression could have appeared to be an overstatement. But fourteen years ago the man-in-the-street was quite unaware of what sort of thing an "internal combustion engine" might be, if indeed such a thing existed. Moreover, until that time no engineering writer had even dared to put so unfamiliar a title on the cover of his book. Gas engines, oil engines, and petrol engines were of course known, but it was scarcely suspected that apparatus of that sort was likely to have any primary effect on world history.

Who would have then divined that the introduction by Daimler, fourteen years still earlier, of the high-speed petrol engine was of such potentiality that it would become a debatable point whether our "sure shield," the British Navy, should be allowed to have its Singapore base strengthened, in advance of the provision of an adequate home defence force of those aircraft the very existence of which is one outcome of the pioneer work of Daimler? This is, it is true, merely a military parallel, but equally striking ones could be drawn from civilian activities. The development of internal-combustion-engine road transport is one of the

chief characteristics of the age we live in. Even in England it is sufficiently striking, but in the United States one person in every ten, man, woman, and child, has an automobile; an average of one to every alternate household. Even so the continued output of the Ford factory is measured in thousands of cars per day. America may be a land of wide spaces, but if this rate should continue it is not difficult to foresee a further field for the activities of "control" societies, this time aiming at control of the Ford "birth rate."

The growth of road transport was not due to the stimulus of the War: it was in full steady growth before 1914. But in the case of aviation, the future of the aero-engine as a prime mover is, and must be, vitally affected by the stimulus which grew from the War and still continues. During the War itself the best scientific and engineering talent was encouraged by every possible facility, and by lavish outpourings of money, to produce yet newer and newer developments of the internal combustion engine—whether for aviation, tanks, seagoing craft, or road transport; but chiefly for aviation. Aviation offered then a prospect of a way out from what seemed an endless deadlock; people had begun to fear that in the great struggle, there had unconsciously been invented a new, and very unpleasant, way of life. Since then a relatively impoverished world has sought to find less costly means of defence than the old; and the public, led doubtless by the results of certain American experiments, has begun to look towards the relatively cheap defence by aircraft as affording a loophole for escape from financial burdens which might threaten to become overwhelming. As a mere business proposition, therefore, it "pays" to encourage aviation, and the surest path of progress in this sense lies in the development of improved aero-engines which shall be of unprecedented power, of extreme lightness, and yet be able to operate with equal facility at any altitude and at any temperature.

One of the pioneers in this necessary development of the internal combustion engine is Mr. Ricardo. We reviewed some little time back the first volume of his book (NATURE, January 13, p. 43). That volume dealt mainly with the older slow-speed engine. The second volume is concerned with the high-speed engine and with its utilisation for certain specialised purposes. It is a fine record of scientific research work; carried out in no small measure by Mr. Ricardo himself, or by those with whom he has been associated, directly or indirectly, through the medium of the Aeronautical Research Committee.

We are well acquainted with most of the books on this subject which have appeared during say the last twenty years, and it is striking to reflect on the change in the point of view shown by the writers at the beginning of that period and at the end. If Mr. Ricardo be taken as typical of the modern writers, and to do so is to pay them compliment, it will be seen from even a cursory survey of the present volume that nothing, however traditional in the art, is taken for granted. Each problem is stated in scientific language, and critically and dispassionately examined: very often the results are unexpected, but whether strange or not, this critical review of them has the immense merit that a chain of possible causation is constructed to which new links can be added, by those who have scientific imagination and insight, leading to new lines of development. Each piece of analysis in fact is made to carry within it the germ of the next step forward.

The mere bulk and weight of Mr. Ricardo's two volumes is forbidding, and might with advantage have been lessened. That, however, is probably more a matter for the publishers than the author. The author has done his part of the work well, though the book would certainly have gained by the freer use of the blue pencil. We have found very few mistakes, though the puzzling letter-press associated with figure 33 on p. 121 does not seem to us to make the carburation procedure represented intelligible to the average reader.

Mr. Ricardo is evidently not satisfied with the present position as to fuel supplies. As is well known, much of his own research work has been devoted to fuel questions —his investigations for the Asiatic Petroleum Company he has fortunately been in a position to make public: much to the credit of that firm. We quote from the present volume: "The mobile internal combustion engine is now no longer a luxury; it has become one of the prime necessities of peaceful civilisation and the prime necessity in time of war; therefore, the assurance of its fuel supply should be considered a matter of national importance. It is perfectly well known that alcohol is an excellent fuel, and there is little doubt that sufficient supplies could be produced within the tropical regions of the British Empire, yet little or nothing is being done to encourage its development." It must be remembered, however, that although plants well suited for the production of alcohol are easily grown in, say, tropical British Africa, it is likely to be a costly matter with present facilities to collect and deal with the material on the spot; hence it is reasonable that a very strong case should be put up by the engine users before steps are taken to embark on large schemes for power alcohol production.

Lest it should seem that the high-speed engine is being considered too exclusively and the older engine ignored, Mr. Ricardo puts his view on record: "That the internal combustion engine has found its ultimate sphere in the light mobile high-speed type is now evidenced by the fact that, whereas in the years

immediately before the War the annual output in horse power of both the light and heavy type in this country was about equal, to-day the aggregate annual power output of the light high-speed type is at least ten times that of all other types, and in numbers probably nearer twenty times."

We welcome this book, and we congratulate the author upon its production and upon his distinguished share in the campaign towards yet further developments. Those who take their stand with the outposts in this campaign and endeavour thence to discern what yet lies in the lap of time will share with Mr. Ricardo his enthusiasm for one of the most stimulating of adventures in the world of applied science.

H. E. W.

The Secret of Life.

The Mechanism of Life in Relation to Modern Physical Theory. By Prof. James Johnstone. Pp. xii + 248. (London: Edward Arnold and Co., 1921.) 15*s*. net.

THE professor of oceanography in the University of Liverpool is well known as an eminent biologist with strong philosophical leanings and an unusual knowledge of physico-chemical science. So the title of this book and the name of its author lead one to expect something of more than ordinary interest. It may be said at once that this expectation is fully justified, for Prof. Johnstone's book is uncommonly stimulating and represents a real and determined effort towards scientific synthesis.

In the first eight chapters, the subjects of which are the nature of animal life, the sensori-motor system, the principles of energy, the sources of energy, on vital production, brain and nerve, the special nervous mechanisms, and the analysis of behaviour, the author gives the reader an excellent and readable outline, well illustrated with diagrams, of some of the fundamental aspects of physiology and the theory of energy (including the second law of thermodynamics). It is fairly obvious that these chapters are written for the purpose of preparing the uninstructed reader to understand what is to follow, for it is in the last three chapters, on the mechanistic conception of life, the meaning of perception, and the nature of life, that we come to the kernel of the matter.

In the first of these chapters the author describes the mechanical system of Descartes. Having disposed of Descartes, he then proceeds to demolish Jacques Loeb, in other words, he finds the modern physico-chemical "mechanisms of life" equally unsatisfying, equally mechanical. But the last paragraph of this chapter, like the concluding sentence of one of those serial instalments of "blood and passion" that appear in certain magazines, shrewdly whets our appetite: "Anyhow, our mechanism of the organism has come again to a crisis. First of all it was a mechanical explanation of life, and that being insufficient, biology resorted to a physico-chemical explanation, which was also insufficient, since physics and chemistry are again becoming mechanical. Looking about for the new conception that biology has now again to borrow from physics, we have little difficulty in finding it, and it would appear as if it were really something new. The concept is given to us in the physical notion of statistical mechanics and to this we shall return presently."

This sounds exciting, though it is not quite evident at first sight why statistical mechanics should be any better than mechanics. However, the secret comes out in the last chapter, which treats of "The Nature of Life." Here the author deals in a very interesting way with the laws of thermodynamics, his discussion being based on the statistical methods of Boltzmann and Smoluchowsky. It is pointed out that the universe "becomes a cyclic order, such that the most probable phases are those in which entropy tends towards its maximum value, and the least probable ones are those in which the entropy tends towards its minimum value. As such it is a permanent universe, self sufficient, without beginning and without end."

Proceeding from this basis, the author arrives at the following result. In inorganic processes and tendencies available energy runs down and entropy increases; whereas in "vital" processes and tendencies available energy accumulates and entropy decreases. Summing up, he states that "In living processes the increase of entropy is retarded. This is our 'vital concept'." His exact meaning will be rendered clearer by the following quotation. Discussing the photosynthetic action of the green leaf, he says: "Starch accumulates in the green leaf exposed to sunlight, but the *whole* system is the green leaf + the CO_2 and H_2O + the 'degrading' sunlight. In the system thus defined entropy increases very slowly. The system is one in which there are *coupled* energy transformations. (1) the degrading sunlight; and (2) the photosynthetic process. If there were no coupling, the solar energy would degrade, with a maximum entropy increase; if there is a coupling the entropy increase becomes minimal. The coupling is always the mark of life activity."

Suppose we illuminate some oxygen at room temperature with the right sort of ultraviolet light. Some ozone is formed. In this *inorganic* system we have two coupled energy transformations, (1) Oxygen ⟶ Ozone, with increase of free energy and diminution of entropy; (2) "degrading" ultraviolet light, with diminution of free energy and increase of entropy.

Suppose again that we shake a solution of oxygen in water with zinc filings. Some hydrogen peroxide and some zinc hydroxide are formed. Here again we have an inorganic system and two coupled energy transformations, (1) Oxygen + Water $\longrightarrow$ Hydrogen Peroxide, with increase of free energy and diminution of entropy; (2) Zinc + Oxygen + Water $\longrightarrow$ Zinc Hydroxide with decrease of free energy and increase of entropy.

Hundreds of such examples might be given. For example, by a suitable coupling of voltaic cells we can realise the pair of coupled transformations, (1) $H_2 + I_2 \longrightarrow 2HI$ *aq.*, with increase of entropy; (2) $2HCl$ *aq.* $\longrightarrow H_2 + Cl_2$, with decrease of entropy. Thus, a coupled transformation involving, when taken by itself, a decrease of entropy, is no prerogative of the living cell or organism. The latter is not a bit from an "improbable" part of the universe, which is retarding or reversing the operation of the second law of thermodynamics in our particular part of the universe. A living cell or organism does not, as it were, act spontaneously. If we could photograph Mr. Home in the act of "spontaneous levitation," we could wager quite safely on the existence of a "coupled degradation," even if we could not see it. The continued activity and existence of a living organism depend on its utilisation of an environment which is not in perfect thermodynamic equilibrium. The totality of the actions involves a decrease of free energy (increase of entropy), while a part will in general involve a "storing of availability," *i.e.* an increase of free energy and a decrease of entropy. But this is a general characteristic of most complex physico-chemical actions and reactions, including also the physico-chemical actions and reactions of the living organism and its environment. These facts are, of course, well known. The late Prof. Benjamin Moore often pointed out that the living cell acted as an "energy transformer." What he really meant was that it acted as a transformer of "energy potential," running some energy up to a higher "potential," and some down to a lower "potential," like an electrical transformer. If such coupled transformations never occurred in what we call the inanimate world, then we might find here a real prerogative and characteristic of vital activity. But the existence of such coupled "up-and-down" transformations in the inorganic world is the commonest of occurrences. The inorganic world in its various transactions does not, in fact, only "go down hill." The progress of the rake is zigzag, and not wholly a piece of undiluted villainy.

In trying to gain an understanding of the totality of the actions of a living organism, it appears to the reviewer that we may have to seek it in the intimate actions or "behaviour" of particular individual entities, rather than in the average statistical behaviour of "crowds." A piece of radioactive material decays according to the mathematical laws of continuous change, but behind this apparent continuity there lies a series of discontinuous changes or "mutations." The apparently continuous activity manifested in an ordinary chemical reaction, which can also be represented by the mathematics of continuity, is due in reality to a hidden series of "critical" states and "critical" transformations. Everywhere the "evolutionary changes" of individuals appear to be of a discontinuous, critical, or mutational type. Behind or below the determinism of our statistical laws of physico-chemical change there lies a deeper determinism based on the transformations of particular individuals at particular moments. Modern physico-chemical science has already obtained a large measure of success in analysing this apparent "spontaneity" and in discovering the intimate laws of action of individuals. The City Actuary is being replaced by the Harley Street physician. Meanwhile, the philosopher with his *élan* of impatience (and ignorance) hurls defiance at the harmless corpse of the older determinism.

Prof. Johnstone's book contains much more, however, than his attempt to find a characteristic or criterion of vital activity in statistical mechanics. It deals with such subjects as perception, behaviour, mind, memory, freewill, habit, etc., and attacks the doctrine of determinism as applied to the deliberative actions of animals. Thus the author says: "In most animals there is some indetermination and spontaneity of behaviour, and the more highly organised is the central nervous system, the greater seems to be the degree of indetermination that is exhibited." In much of this discussion he reveals himself as a follower of Bergson.

Finally, Prof. Johnstone, the philosopher (as distinct from the psychologist and biologist) allows himself the luxury of what he calls a "metaphysical discussion," which, however, he relegates to an appendix. We need not follow him into those "faery lands forlorn." Philosophers (*i.e.* the professional sort) live by taking in each other's washing, and it is no part of good manners to interfere with these detergent ceremonies.

The general impression which one gains from this book is that the author is dissatisfied with the present-day physico-chemical description of biological sequences. But it does not appear that he has anything better to offer. We have seen that his thermodynamical (or statistical mechanical) discussion provides nothing new. He brings in the modern physical theory of relativity and seems to find some comfort in the reflection that

the electrons, atoms and molecules, when going about their lawful occasions are, after all, only successive space-time coincidences. But so, also, are the biological sequences !

Nevertheless, Prof. Johnstone's book is the work of an honest, mature and determined thinker, who possesses a good knowledge of physics, chemistry, and biology. As such it is worthy of very serious consideration and thought, and constitutes a most interesting contribution to scientific literature.

F. G. DONNAN.

The Geological Description of Britain.

(1) *Memoirs of the Geological Survey: England and Wales.* Explanation of Sheet 96: *The Geology of Liverpool, with Wirral and part of the Flintshire Coalfield.* By C. B. Wedd, B. Smith, W. C. Simmons, and D. A. Wray. Pp. vi+183. 4s. net.

(2) *Memoirs of the Geological Survey: England and Wales.* Explanation of Sheet 169: *The Geology of the Country around Coventry, including an Account of the Carboniferous Rocks of the Warwickshire Coalfield.* By T. Eastwood, Dr. W. Gibson, T. C. Cantrill, and T. H. Whitehead. With contributions by Dr. H. H. Thomas and the late C. H. Cunnington. Pp. viii+149+8 Plates. 5s. net. Also Sheet 169, 1 inch to 1 mile, colour-printed, Drift edition, 2s.

(3) *Memoirs of the Geological Survey: Scotland. The Geology of Corrour and the Moor of Rannoch* (Explanation of Sheet 54). By L. W. Hinxman, R. G. Carruthers, and M. Macgregor. With contributions by the late Dr. C. T. Clough, and Petrological Notes by Dr. H. H. Thomas and H. H. Read. Pp. iv+96. 4s. net. Also Sheet 54, 1 inch to 1 mile, colour-printed, Drift edition, 3s.

(Southampton: Ordnance Survey Office; London: E. Stanford, Ltd., 1923.)

UNDER the direction of Dr. J. S. Flett, the Geological Survey of Great Britain, with its happily increased emoluments and staff, remains one of the most progressive scientific institutions in the British Isles. The first two memoirs here noticed are based on the revision of mapping done in earlier days, and they form an effective answer to those who hold that geological observations once recorded are incapable of improvement in the light of later knowledge.

(1) The account of the Liverpool district is appropriately published in time for the visit of the British Association. Details derived from mining developments have been utilised, and twenty-four shaft-sections in the Flintshire coalfield are represented in a plate. The account of the recent improvements in water-supplies (pp. 127-147) records the great success of the Vyrnwy reservoir, which was completed in 1892, only 7·2 per cent. of the water used by Liverpool being now drawn from wells in the Bunter beds that underlie the city. The case of Holywell in Flintshire down to the days of the War, when the water was carted to the upper part of the town from the holy well of St. Winifred, and then dispensed in buckets, is quaintly described. This supply was seriously reduced in 1917, by being tapped by mining operations, and at present a reservoir is being utilised to receive water pumped from neighbouring shafts.

The glacial deposits of the district now receive concise description, based upon studies by Mellard Reade, G. H. Morton, and others, who have made Liverpool famous as a centre of geological observation. Important modifications have, however, been made in older views as to the mode of deposition of the drifts, and it is well to have the evidence of the striation of the rock-floor by ice from the Irish Sea conclusively put forward (p. 96). The glacial striæ occur mainly near the coast; they are directed to the south-east; and 58 per cent. of the boulders from a clay-pit in Stanley Road (p. 95), examined by Morton and Goodchild, showed striations on their surfaces. The list of erratics includes rocks from the county of Antrim, Ayrshire, Ailsa Craig, and the Isle of Man. The evidence for the existence of a great Irish Sea glacier is here complete.

(2) The memoir on the "Country around Coventry" is in reality a description of the area of the accompanying Sheet 169 of the colour-printed one-inch map, and covers the very interesting district north and north-east of the city. The whole of the Warwickshire coalfield, which extends into Sheet 155, has, however, been included in the memoir. Educationally, the map is a fine one from the contrast in structure of its eastern and western areas, the Cambrian shales and quartzite coming in west of the great fault, and underlying the Middle Coal-measures, while the drift-covered Triassic country to the east includes the remarkable inlier of ancient quartz-diorite, formerly styled granite, that is quarried at Lane's Hill.

It is suggested on p. 20 that this and the similar rock of Mount Sorrel, which formed part of the land-surface in Triassic times, may be of Devonian age, like the granites of the Lake District and of southern Scotland. We note among the geographical features the growth of Coventry in consequence of the mining activity north of it (p. 1), and on the map the grand old line of Watling Street, with the main route of the London, Midland, and Scottish Railway, keeping similarly to the Triassic lands.

(3) The third memoir dealt with in this notice leads us to a very different country. The Moor of Rannoch

has now been traversed by the railway to Fort William; but its essential wildness remains, and has become known to thousands who otherwise could have realised little of the grimness of the central highlands. We are here on the watershed between the North Sea and the western inlets, and its rugged characters seem typified in the trench-like hollow in which Loch Ericht lies (p. 9). The contoured geological map, with its audacious mass of scarlet where the early Devonian granite forms the moorland, should be studied side by side with the hill-shaded sheet of 1876, on which Mr. R. McFadden gave us what is surely one of the finest examples of hachuring in the world.

The question of recumbent folds among the metamorphosed stratified series has been raised by Mr. E. B. Bailey, and the views of the official geologists in this difficult region show healthy differences that will stimulate yet further work. By any one who has emerged on the moorland from the deep cleft of Glencoe, the courage of those who have investigated the district yard by yard must be gratefully acknowledged and admired. The most striking feature of the description of the glacial deposits is the evidence that boulders of the Rannoch granite have been abundantly lifted by the land-ice to heights of 1000 feet above the level of the moorland mass. G. A. J. C.

Medical Science in the War.

History of the Great War: Based on Official Documents. Medical Services: Diseases of the War. Vol. 2: *Including the Medical Aspects of Aviation and Gas Warfare, and Gas Poisoning in Tanks and Mines.* Edited by Maj.-Gen. Sir W. G. Macpherson, Maj.-Gen. Sir W. B. Herringham, Col. T. R. Elliott, and Lt.-Col. A. Balfour. Pp. viii + 621 + 7 plates + 6 maps. (London: H.M. Stationery Office, 1923.) 25*s*. net.

AS the details of the War fade away into the past, our perspective of the ordeal emerges more and more clearly, and when viewed from a distance of five or more years, the magnitude of our effort begins to make itself apparent. Time, if it has not yet healed our wounds, has at least enabled a considered diagnosis and history to be made. How wonderful that history was, how resourceful our resistance, how well-earned our victory, can be gathered by reading this truly fascinating account of the work of the Medical Services during the War. Never before in war has the air played so big a part; its physical properties have loomed large in problems of aviation, while its importance in respiration has made physiology one of the most indispensable of sciences in connexion with aviation, gas warfare, and mining operations.

Application of the results of scientific research led to the solution of most of our difficulties. By careful tests men could be selected who were physiologically suitable for flying, while those unfit could be eliminated; "flying strain" could be detected and treated; by the use of liquid oxygen aviators could reach heights otherwise unattainable, and still retain their efficiency. Many lives were saved, and considerable advantage gained in consequence.

After that portentous experiment of April 22, 1915, when the aspect of warfare was changed by the use of asphyxiating gas by the Germans, stupendous efforts were made to devise protection against this form of attack. For a while, gas offensive and anti-gas protection strove, on either side of that awful strip of neutral land, each to outdo the other; the ultimate victory was with the defence.

That the British box respirator was easily the best in the field cannot be denied by any one who knows all the facts, for it was satisfactory both from the chemical and physiological point of view, and hence this form of respirator was greatly in demand not only for the use of our own troops, but also for those of several of our allies. Its evolution from less perfect predecessors is fully explained in the tenth chapter of the book. Chapter ix. contains a full account of several gas attacks made upon our troops; in one case at least the reviewer can testify to the complete accuracy of this official account, and has no doubt that all the other accounts are equally accurate, since they were written up in the field by exceptionally able Army chemical advisers, on the basis of verified reports by the units concerned.

Gas warfare reached a crescendo in July 1917 when mustard gas was first employed, and the number of casualties suddenly jumped up, and even with the most stringent precautions remained high until the end of the War. This was due, not to inefficiency of the respirator, but to difficulties of detection of the gas, and to damage done to the general body surface by the substance. In spite of all our precautions the total reported gas casualties were 180,983, not counting some who died on the spot, or were taken prisoner; something more than 6000 of these died, while about 19,000 had been classed for pensions during the year 1919–1920. This forms about 2 per cent. of the total post-War disabilities, which is only a small number; very few of these men have since died from indisputable effects of gassing. The medical treatment of gas-poisoning may therefore be said to be fairly satisfactory, and is fully discussed, together with the pathology of gas-poisoning, in the official account.

Much has been written elsewhere about gas warfare; it has been described as a cheap, effective, and humane means of attack, and also as the most costly, most

ineffective, and most brutal weapon yet devised. That it has come to stay is certain; that it cannot be ignored is incontestable; that it may even be the means of ultimately extinguishing the civilisation which has engendered it seems not impossible. No one could read this considered account without being impressed by its fundamental significance.

There is one gas against which the respirators are not effective; this is carbon monoxide. It was not, and could not easily be used as a means of attack, but was encountered in ill-ventilated tanks and in mines after a blow had occurred. This danger was met, as similar danger is met in coal mines, by the use of some form of oxygen respirator. Mine rescue work, and the treatment of carbon monoxide poisoning, form the concluding chapters of this valuable and interesting document.

The Foundations of Future Psychology.

The Nature of "Intelligence" and the Principles of Cognition. By Prof. C. Spearman. Pp. viii+358. (London: Macmillan and Co., Ltd., 1923.) 15*s.* net.

"IN these principles, then, we must venture to hope that the so long missing genuinely scientific foundation for psychology has at last been supplied, so that it can henceforward take its due place along with the other solidly founded sciences, even physics itself. In particular, these principles (together with commentaries upon them) appear to furnish both the proper framework for all general text-books and also the guiding inspiration for all experimental labours."

This is the author's very confident conclusion. The source of cognition, he holds, is experience. This he defines as "that which is immediately lived, undergone, enjoyed, or the like"—a definition which would appear to include digestion and the hardening of one's arteries.

The first intelligent operation is the apprehension of experience. This is said to include sentience, affection, cognition, conation, and the *ego*. The inclusion of the *ego* is firm but apologetic, "pending some much more plausible alternative explanation being proffered." It is hinted (but not argued) that the fundamental connectedness of these items is also apprehended at this primary level.

The second principle—the "eduction of relations"—states that "the presenting of any two or more characters tends to evoke immediately a knowing of relation between them." The proof of this "tendency towards evocation" appears to be that these relations may be discovered. These relations include all the categories—time, space, causality, and the rest. All are neatly ticked off.

The third principle—the eduction of correlates—is that "the presenting of any character together with a relation tends to evoke immediately a knowing of the correlative character." This principle is very thoroughly elaborated and illustrated.

These principles and their manifestations are called "noegenetic" because they are "noetic" (self-evident) and generate further knowing. They are "the principles of intelligence" and fundamental for cognition.

The book, we are told, is "solely psychological and by predilection practical." The author, in consequence, believes himself justified in adopting the methods of a drumhead court-martial on the frequent occasions when he tackles metaphysical points. Since the essence of his argument, however, is noetic self-evidence, it is difficult to understand what he means by unadulterated psychology. Certainly he makes a most resolute attempt to illustrate and corroborate his results from laboratory evidence; and this is the most valuable, as it is also the most distinctive, feature of his discussion. He is far too clear-headed, however, to mistake corroborative for fundamental evidence.

Take, for example, one of his favourite topics—the initial status of sense-experience. Neither his choice of this topic nor the greater part of his treatment appears to be predominantly psychological. He begins with the argument commonly known as physiological scepticism, and ignores the vicious circle it contains. Satisfied with this, he appears to rely on self-evidence until quite late in the work, when he brings corroborative experiments to bear upon his implied assumptions concerning this "tremendous problem of objectivity." It is true that he assigns to these experiments much greater value than is due: but his fallacy is logical, not experimental. To pass other points, the brunt of his discussion here concerns subjectivity in the sense of "actually constituting your state of consciousness as when you say 'My consciousness was that sensation.'" Since many philosophers hold that no one can ever truthfully say any such thing, it is plain that this "experimental" question is a flagrant *petitio principii*.

The same remarks seem apposite when the author deals expressly with "transcendence." It is clear to him that somehow we come to know what is not a state of ourselves, and he alleges that we do this by educing correlates. We apprehend the *ego*, grasp the relation of otherness, and educe a not-self (p. 107). This looks simple. Self and otherness, together, will give you, of course, "other selves," or "other than any self," or "anything other than yourself." You can therefore "educe" or "draw out from the very nature of the item (yourself) presented" your parents or, if you will, the rest of the universe. In short, anything can be done by these methods, and it is not at all clear why the author did not choose to "educe" "non-experience"

from "experience" or "infinite objectivity" from "finite subjectivity."

These principles are called "qualitative," but there are also five "quantitative" ones, and three further "anoegenetic" principles of reproduction, disparition, and variation of clearness. I have space only for a few remarks on these heads.

The first three of the five quantitative principles run as follows: (1) Every mind tends to keep its total simultaneous cognitive output constant in quantity however varying in quality; (2) the occurrence of any cognitive event produces a tendency for it to occur afterwards; (3) the occurrence of any cognitive event produces a tendency opposed to its occurring afterwards.

Of these (1) looks as if it meant that every sleepy mind tended to have the same cognitive output as it has when alert. This, however, is not what is meant. Our author seems to mean instead (p. 131) that the occurrence of any one noegenetic process tends to diminish the others. The second noegenetic process, however, presupposes and includes the first.

(2) and (3) are flatly contradictory, so that it is difficult to know what to do with them. They are called respectively Retentivity and Fatigue. It may be worth remarking, then, that Fatigue, in ordinary language, does not contradict (2). When you are tired you are likely to stop, but *afterwards* you may begin again.

I do not mean these criticisms to be verbal, but I should be glad if they were. For the author's courage and resource I have nothing but admiration, and his vigour is always refreshing. JOHN LAIRD.

Our Bookshelf.

Memoirs of the Geological Survey. Special Reports on the Mineral Resources of Great Britain. Vol. 1: *Tungsten and Manganese Ores.* Third edition. By Henry Dewey and H. G. Dines; with Contributions by C. N. Bromehead, T. Eastwood, G. V. Wilson, and R. W. Pocock. Pp. iv+83+3 plates. (Southampton: Ordnance Survey Office; London: E. Stanford, Ltd., 1923.) 2*s.* net.

THE latest edition of the report on the British ores of tungsten and manganese merely brings up-to-date the information contained in the previous editions, but it cannot be said that it has brought out any new facts of importance. Perhaps it only serves to emphasise the industrial unimportance of the British sources of supply. Temporarily the War directed attention to the domestic sources and caused these to be actively worked, but under post-War conditions, the home deposits have again been found to be unable to compete with the richer deposits that exist abroad. This is well exemplified by the ores of tungsten, the British output of which touched nearly 400 tons per annum during the War, while the output to-day is probably less than a quarter of this quantity; in the same way the price, which during the War reached 55*s.* per unit, is to-day only about 12*s.* Furthermore, the total output from Great Britain is only about 2½ per cent. of the world's production.

In the case of manganese ores the figures show the same tendency, though not to so marked an extent; this is due in part to the fact that the great bulk of the British ores of manganese are of low grade compared to the imported ores. The chief centre of our home supplies is in North-West Wales, in Carnarvonshire and Merionethshire, both of which districts are well described in the present report. These ores appear to average less than 30 per cent. of metallic manganese, while imported ores contain at least 50 per cent. Even so, however, the tonnage of domestic ores is barely 1 per cent. of the world's production, and only about 2 per cent. of our imports. Economically, therefore, the British production of both these ores is negligible, and a careful study of the report before us affords no ground for hope that it will ever become a factor to be reckoned with in the world's markets for either mineral.

Cements, Limes and Plasters: their Materials, Manufacture and Properties. By E. C. Eckel. Second edition, revised and partly rewritten. Pp. xxxi+655. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 32*s.* 6*d.* net.

ECKEL'S treatise on cements, although dealing almost exclusively with American practice, is one of the most thorough works on this subject, and the new and revised edition will be accepted as a standard authority. The scanty references to English practice are not always accurate, and the casual reader might suppose that the industry in Great Britain was insignificant, but the information in regard to the United States and Canada is very full. A more detailed account of the fixed mechanical kilns which are now assuming so much importance would have been welcome, as they are now becoming serious rivals of the rotary kiln. It has been found possible to include a short account of the high-alumina cements recently introduced, although there is no systematic consideration of their properties. The section on slag cements is misleading. Only the older pozzolanic cements, consisting of mere mixtures of granulated blast-furnace slag and lime, are considered, and the much more valuable "Iron-Portland" or "Blast-Furnace Portland" cements, made by mixing a suitable granulated slag with clinker and grinding together, are not even mentioned. The chemistry and physics of cement do not receive attention, the treatment being purely empirical, but within its limits the book gives an excellent survey of an important American industry.

The Causes and Prevention of Corrosion. By A. A. Pollitt. Pp. 230. (London: Ernest Benn, Ltd., 1923.) 25*s.* net.

THE literature of corrosion is extensive, but far from satisfactory in its scientific aspects. There is a large collection of facts, but a singular lack of co-ordinating principles. Each experimenter has his own hypothesis, which fits a small group of observations, but usually breaks down when applied to other, nearly related facts. The writer of the present work has prepared a useful survey of the subject, although confining

himself almost exclusively to work published in English, and without any evidence of first-hand observation. Concrete examples, so important in such a subject as this, are lacking, and the reader is thus little able to judge of the relative merits of the rival hypotheses, which are, however, fairly and accurately described. The corrosion of steel boilers and of brass condenser tubes is treated more fully, the section on the latter subject being reprinted from a pamphlet issued by the Corrosion Committee of the Institute of Metals. The most valuable part of the book deals with the prevention or diminution of corrosion, especially of boilers and condensers. Here the author is evidently at home, and the chapters on the softening and de-aeration of water, and on the protection of boilers by electrolytic methods, are fully illustrated and contain much detail. This portion of the book might well have been issued alone, a procedure which would have lessened its rather high cost. The printing is good, and the illustrations of plant are very clear.

The Bakitara or Banyoro: the First Part of the Report of the Mackie Ethnological Expedition to Central Africa. By the Rev. Canon J. Roscoe. Pp. xvi + 370 + 42 plates. (Cambridge: At the University Press, 1923.) 25*s*. net.

ANTHROPOLOGICAL science owes a debt of gratitude to all who were concerned in the initiation and organisation of the Mackie Ethnological Expedition to Central Africa; but most of all to Mr. Roscoe, by whom the actual work of investigation was carried out. This first instalment of his report is an invaluable contribution to our knowledge, and will prove an almost inexhaustible mine of information for the student of primitive custom and belief. The dominant people of the country of Kitara are the Bahuma, Negro-Hamites, possibly of Galla strain, though this is uncertain. Coming from the north-east, they invaded the country in the lake region immediately west of Uganda, part of which they now occupy, and subdued the Bahera, the agricultural negro aborigines. Among much which is striking in their culture, the most remarkable feature is the manner in which their whole social and religious organisation centres around their herds. The entire routine of the kingly office is ordered solely to promote by sympathetic influence the well-being of the cattle. The elaborate milk ritual, which Mr. Roscoe has studied carefully in minute detail, inevitably invites comparison with the dairy cult of the Todas of Southern India.

L'Homme fossile de La Quina. Par Dr. H. Martin. (Archives de Morphologie générale et expérimentale. Fasc. 15: Anatomie.) Pp. 260. (Paris: Gaston Doin, 1923.) 25 francs.

IN this volume Dr. Martin describes the results of the investigations which he has carried out on the Mousterian site of La Quina (Charente) since 1905. His discoveries included a large number of mammalian remains and of typical implements as well as objects of bone, which at the time of discovery constituted the first evidence of the use of bone in the Mousterian age. Much of this material has formed the subject of communications to French scientific societies, and the general conclusions are well known; but anthropologists will welcome this careful and detailed study of the evidence as a whole. The author, by inference, does much to throw light upon the habits of Mousterian man, and it is noteworthy that he is inclined to regard a certain condition of the equine teeth as evidence for domestication. His most important contribution to anthropological science, however, was the discovery in 1911 of the human skeletal remains now known as the La Quina man, and in 1915 of the cranium of a child aged eight, both falling within the Neanderthal group. Dr. Martin, on the ground of inferiority to type in certain respects, is disposed to regard the former as female.

Practical Chemistry. By E. J. Holmyard. (Bell's Natural Science Series.) Pp. xvi + 267. (London: G. Bell and Sons, Ltd., 1923.) 4*s*. net.

MR. HOLMYARD in the preface to his book has something to say on the heuristic system, about which so much was said a few years ago. While we may admire it at a safe distance, he remarks, "We are at least upon safe ground when we believe that a little sound knowledge acquired by the method of direct teaching is distinctly more valuable than much hazy and inaccurate knowledge gained by the so-called 'method of research'—which is, of course, not the method of research at all, but a sort of game of make-believe." He has written a sound and useful book on the lines he advocates. It covers the ground of the School and Higher Certificate Examinations, and is sufficient for University Scholarships, but is wisely not written for any examination. Gravimetric and volumetric analysis, physical chemistry and organic chemistry are included, but the author has rightly, we think, omitted qualitative analysis. The course described is one of the best we have seen, and the book should become popular in schools. It is evidently the work of an experienced teacher.

Ink. By C. Ainsworth Mitchell. (Pitman's Common Commodities and Industries.) Pp. ix + 128. (London: Sir Isaac Pitman and Sons, Ltd., 1923.) 3*s*. net.

MR. MITCHELL has dealt with the origin of inks, the way in which they are made, and their characteristics in a most interesting and useful way. The use of carbon inks, he shows, dates back to very remote periods in Egypt and China. The earliest mention of iron-gall ink is said to be in the work of Theophilus the Monk, dating to about the eleventh century A.D. Before the beginning of the seventeenth century, ink was made in the household, but in 1609 it was manufactured in Paris, later in Dresden, and much later by Stephens in England. Mr. Mitchell deals with all kinds of ink, including printing ink.

Your Broadcast Receiver and How to Work It: Hints and Tips for the Radio Listener. By P. W. Harris. Second Impression. Pp. 68. (London: The Wireless Press, Ltd., 1923.) 6*d*. net.

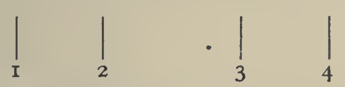
THIS book can be recommended to owners of broadcasting receiving sets. A judicious amount of elementary practical theory is given which will enable them to get the best results from their apparatus.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Regularities of the Spectral Lines of Iron and the Atomic Magnetic Field.

SINCE our short account of the method of observing the Stark effect with a stabilised arc was written (see NATURE, March 31, p. 431), we have made experiments on about twenty different metals. With elements having a simple spectrum, as silver, copper, zinc, and others, the separation of the lines into different series is facilitated from the similarity in the winged appearance of the lines in the strong heterogeneous electric field near the anode, though the broadening is generally asymmetric and there is some difference among the polarised components. The examination of many thousands of iron lines is not yet completed, but choosing lines between λλ 2400 to 3000 Å showing the simplest type of the effect, in which they are enhanced and slightly shifted towards shorter wave-lengths, we have found that a few lines can be arranged in regular triplets, quartets, and sextets. These mostly belong to spark lines. In addition to these regularities, we can arrange the enhanced lines into a large number of quadruplets as shown below:



The frequency difference, $\Delta\nu(1,2)$, is equal to $\Delta\nu(3,4)$ to a fraction of the wave-number per cm. The relations between $\Delta\nu(1,2)$ and $\Delta\nu(2,3)$ are various, but the values of $\Delta\nu(2,3)$ and $\Delta\nu(1,4)$, and especially those of $\Delta\nu(2,4)$ and $\Delta\nu(1,3)$, are common to many of the quadruplets.

The remarkable numerical relation between $\Delta\nu(1,2)$'s is that they come out in groups as given in the subjoined table:

Group.	No. of Quadruplets.	Mean $\Delta\nu(1,2)$, $\Delta\nu(3,4)$.	Range of $\Delta\nu(1,2)$.
a	14	59·6	55 to 68
b	15	111·7	106 to 121
c	46	182·4	171 to 197
d	34	245·3	230 to 262
e	6	362·9	354 to 372
f	47	422·4	414 to 435
g	15	484·9	477 to 495

Values outside the ranges above cited do not appear.

Counting from group (*a*), the mean $\Delta\nu(1,2)$'s, excepting the second, are almost exactly in the ratio

$$1:2:3:4:6:7:8.$$

It is singular that 5 does not enter in the above ratio; the absence of this number will probably underlie the principle of choice. Perhaps the above ratio has some bearing on the quantum theory, and is connected with the inner quantum number (" innere Quantenzahl "). If we interpret the existence of regular separations as due to the action of an atomic magnetic field, the above relation seems to be one aspect of Runge's rule in the Zeeman effect. Taking 363 as the standard separation, the above ratio can be written as representing 1/6, 1/3, 1/2, 2/3, 1, 7/6, 4/3. The intervals of quadruplets in group (*g*), for which $\Delta\nu(1,2)=485$, frequently occurs and is closely related with the separations of numerous quadruplets, so that it seems to have some important signification. The same number occurs in two regular triplets.

In forming these quadruplets, there is no criterion but that of taking the interval $\Delta\nu(1,2)=\Delta\nu(3,4)$, with corresponding symmetry in the intensity of lines. Analysing the distribution of lines, it is found that the same line can be looked upon as belonging to more than one quadruplet. Most of them are perhaps not real quadruplets, but belong to portions of more complex separations, the true nature of which is difficult at present to unravel. Dealing with many hundreds of lines, chance coincidences may frequently occur, yet the probability of the existence of regularities can scarcely be doubted. Eventually, we shall be able to arrange the iron lines in spectral series by utilising the Stark effect, if such really exist.

If we assume that the separations are due to the Zeeman effect of the atomic magnetic field, they will probably amount to aliquot parts of a normal triplet, if they follow Runge's rule. This is not usually obeyed in iron lines by applying an external field, but if we roughly assume that the triplets ($\Delta\nu(1,2)=485$) are normal, the field must amount to 10^7 gauss, which will approximately give the order of magnitude of magnetic force acting on the light-emitting electrons. As the above value of $\Delta\nu$ corresponds to the widest separation observed, the field will be generally smaller; by choosing $\Delta\nu=354$, which is found in one of the triplets and a number of quadruplets, the atomic field is found to be 6.6×10^6 gauss, coinciding with the value found by Weiss from experiments on magnetisation. This gives strong support to the magneton theory, and though the problem of atomic field is still in a hypothetical stage, the close agreement of the results obtained from measurements made on different phenomena is worthy of further consideration.

In Bohr's equation for calculating the frequency of light, the change of electric energy is taken into account only when an electron passes from one orbit to another during the emission of light. If we assume that, in the interior of an iron atom, a strong magnetic field as given above is prevalent, we must also examine the change of magnetic energy during the emission. This adds a further complication to the discussion, especially when the orbits are not coplanar. The question is, where does the magnetic field come from; does the seat lie in the nucleus or in the orbital motions of electrons? The intricate nature of the spectral lines in ferromagnetic metals may ultimately be traced to the existence of an inner atomic field.

The list of lines and different separations will be published shortly in the *Japanese Journal of Physics*, vol. 2.

Hongo, Tokyo, July 20.

Embryology and Use-Inheritance.

HAVING read with great interest in the supplement to NATURE of August 18 the Huxley lecture of my friend Sir Arthur Keith, and the comments upon it in " Current Topics and Events " of the same issue, I should like as an embryologist to make some remarks on the subject. Sir Arthur, in his fascinating style, describes the manner in which during development indifferent embryonic cells are marshalled so as to build up structures of functional and adaptational use. He arrives, however, at the surprising conclusion that " functional adaptation . . . is a property

resident in the embryonic tissues; the effects of usage in the parent can have no influence on the machinery."

Sir Arthur, therefore, if I understand him aright, comes out as a predestinarian orthogeneticist. The experiences of the animal have no influence in shaping the structure of its offspring. In this attitude he outdoes that ultra-mendelian Prof. Morgan, of New York, who, when confronted with the problem of the ultimate causes of his "mutations," admitted that no other source could be found for them except the influence of the environment.

What reasons does Sir Arthur adduce for what I may term his despairing conclusion? In the last analysis they reduce themselves to two, namely: (1) functional adaptations—such as the shape of the crowns of the molar teeth—and the separation of the peronæus tertius muscle from the extensor muscle of the little toe, come into existence in the embryo before there is any possibility of the performances of the functions to which they are adapted; and (2) Sir Arthur can conceive of no mechanism by which the habits of the parent can influence the embryonic machinery.

Now when Lamarckism is dismissed on grounds such as these, it would have been just as well if Sir Arthur had made himself acquainted with the form in which the Lamarckian theory is held by modern biologists. May I briefly refresh his memory? Modern Lamarckism may be stated as follows:

(1) An animal exposed to a new environment modifies its habits, so as to adapt them to new needs.

(2) New habits, persistently indulged in, entail modifications of adult structure.

(3) The offspring of animals which have adopted the new habit, if they remain in the same environment as their parents, tend to assume the new habits more quickly and on slighter stimulus than did their parents, and to develop the corresponding structures at an earlier period of their lives.

(4) Ultimately, when the new habits have persisted for a long time, *the corresponding structures make their appearance in development before the performance of the functions to which they are adapted.*

It is obvious, therefore, that all Sir Arthur Keith's arguments against "use-inheritance" are irrelevant to the question at issue. Sir Arthur is a brilliant mammalian embryologist. Were he a comparative embryologist he would be acquainted with cases which would stagger even him in his opposition to Lamarckism. I will give one. All Macruran crustacea (lobsters, prawns, shrimps, etc.), when seeking retreat, move backwards and strive to thrust the abdomen into a dark crevice. The hermit crabs have adopted the habit of inserting the abdomen into the curved passage of an empty gastropod shell, and in consequence the abdomen has become curved. The young hermit crab, however, in its last free-swimming stage has an abdomen as symmetrical as that of a shrimp; but when it sinks to the bottom, *before it has found an appropriate shell*, the abdomen has already become curved. Does Sir Arthur ask us seriously to believe that this curvature has been produced by some mystical "adaptational" mechanism among "embryonic cells," and has had no relation to parental habits? The paragraph in "Current Topics and Events" rightly states that the crux of the whole discussion is the proof of the actual existence of use-inheritance. Many of us believe that by means of well-thought-out and patiently executed experiments this proof has already been given. Those who refuse their assent may be divided into two classes, namely: (*a*) those who are unacquainted with the full details of the experiments; (*b*) those who are acquainted with these details and strive to escape from their inevitable consequences by attributing fraud to the experimenter. It is obvious from his sympathetic references to Kammerer that Sir Arthur Keith belongs to the first of these categories. May I recommend to him a more prolonged and extensive study of Kammerer's papers?

The paragraph in "Current Topics and Events" goes on to state that every failure to demonstrate use-inheritance strengthens the Darwinian position, which is adopted by the best and most philosophical workers in biology to-day. This is a statement which I frankly fail to understand. Darwin was until the close of his life a convinced believer in the existence of use-inheritance, although he did not regard it as the sole factor in evolution. Who are at present the best and most philosophical workers in biology is, of course, a matter of opinion: I should think that Darwin, if still with us, would put in this category those who had the widest acquaintance with facts. If this criterion be granted, then I may remark that the best palæontologists and the best systematic zoologists whom I know are strongly inclined to adopt the Lamarckian point of view.

Far be it from me to say a single word in disparagement of that great biologist Huxley, whom Sir Arthur Keith claims, and I have no doubt rightly, as a predeterminist. From Huxley I received my first attraction to the study of biology, and it has fallen to my lot to succeed him in his chair. I am convinced that if Huxley were still alive, and had learned from Sir Arthur Keith's brilliant exposition the wonderful facts of the indifference of embryonic cells, and their capacity at need to form any kind of tissue, he would find it difficult to persist in his conception of the "germ-plasm" as a machine-like mosaic of molecules.

Sir Arthur compares the embryonic cells to an army of workmen capable of various tasks whose energies are co-ordinated to a common end—not by a director but by hormones or chemical messengers which they send to each other. I must frankly confess that it baffles all my powers to conceive how, from an unorganised mob of undifferentiated cells, an organised structure could arise solely by their mutual influence. Certainly the amount of constructive work accomplished in these circumstances by a crowd of British workmen would be a minus quantity. Surely the influence which organises and marshals these cells must be one external to themselves. There must, in the developing embryo, be some part which takes the lead and emits the primary hormones which control the action of the rest. This I pointed out in my address to Section D of the British Association in 1916. May I illustrate this by an example taken from a recent paper by Ruud and Spemann with which Sir Arthur is possibly not acquainted? If a small portion of the developing nerve-plate of *Triton alpestris* be grafted into the ectoderm of a gastrula of *Triton tæniatus* in a region where normally the neural plate is not found, it will organise the ectoderm cells around it into a neural plate, in the midst of which it will be found, distinguishable from the cells of the host by its different colour.

Let me in conclusion suggest to Sir Arthur Keith that these primary hormones or "formative stimuli," which initiate development and give it its course, are the physical correlates and bearers of the *memories* of the race, stored in the egg-cell which has in turn received them from the tissues of the parent generation.

E. W. MACBRIDE.

As I read over the homily which my friend Prof. MacBride has addressed to readers of NATURE in general and to myself in particular—one with which we are all becoming familiar—I was reminded of an

experience suffered by Huxley when he lectured at the Royal Institution on the cerebellum. At the end of the lecture, a devout hearer approached to inform him that she had understood and enjoyed the lecture —with the exception of one point—was the cerebellum inside or outside the skull? After I have filled 24 columns of your valuable space to prove that Huxley was altogether right when he denied that use-inheritance played any part in the evolution of man—or of any other animal—Prof. MacBride, after reading these columns, turns round and practically asks me if I have heard of Kammerer!

If Prof. MacBride will be so good as read my Huxley lecture again, he will see that I neither affirm nor deny the doctrine of use-inheritance What I have denied, in as clear terms as are in my vocabulary, is that Lamarckism—whether of the original 1809 vintage or of the brand bottled in 1923 by Prof. MacBride—has had no part in the evolution of man. To give my reasons for this conclusion would compel me to inflict on the readers of NATURE a repetition of my Huxley Lecture. Here I must content myself by saying that Lamarckism gives no explanation of man's developmental history, none of his anatomy; it leaves the ancestral forms of man, such as we know of from the discovery of their fossil remains, unexplained; it cannot explain the characters which differentiate one racial type of modern man from another. In brief, the tenets which Prof. MacBride clings to with such fidelity cannot serve the purposes of even a working hypothesis for the modern anthropologist.

Prof. MacBride is good enough to suggest that I should be staggered did I know of certain facts with which comparative embryologists are familiar. Well, I do sometimes make little excursions into the realms of invertebrate embryology and frankly confess I am staggered by the fact that men who are familiar with the developmental histories of invertebrate animals can have any belief of Lamarckism as a factor in evolution. ARTHUR KEITH.

Solar Activity and Atmospheric Electricity.

DR. BAUER'S courteous attempt (NATURE, August 11, p. 203) to reconcile our views respecting the connexion he believes in between sun-spots and atmospheric electricity calls for a reply. I should first explain that we differ as regards even the connexion between sun-spots and terrestrial magnetism. Apparently we both accept the relation

$$R = a + bS \quad . \quad . \quad . \quad . \quad (1)$$

between R, the range of the regular diurnal variation for the year, and S, the sun-spot number. Here a represents the range for no sun-spots and $100b$ the increase in range for a sun-spot frequency of 100. The value of $100b/a$ varies with the magnetic element and with the station, but is usually in the neighbourhood of 0·8. The further relation mentioned by Dr. Bauer, p. 204, "an increase of 100 in the sun-spot number would correspond to a decrease in the intensity of magnetisation of the earth of about 0·1 per cent.," is not a result I consider proved. If it were true, there should be a decided 11-year period in the secular change. Claims to have established such a period have been made, but seem to me to have broken down. Quite recently failure to detect the phenomenon at Paris, one of the most satisfactory stations, has been announced by M. A. Angot (*Ann. de l'Institut de Physique du Globe*, Paris, 1923, p. 288). But if Dr. Bauer and I are not exactly at one on this point, we are at least agreed that the influence of sun-spots on the absolute values of the magnetic elements is exceedingly small, if not zero.

Coming now to the potential gradient of atmospheric electricity, Dr. Bauer claims to have established a *substantial* spot influence both on the amplitude of the diurnal variation and on the mean value for the year. In the Physical Society paper to which he refers (Proc. Phys. Soc., London, vol. 35, p. 129), I attempted to check the alleged sun-spot influence both for the diurnal range and the absolute value by means of formula (1). In the case of the absolute value, R represented the mean value of the potential gradient for the year. In addition to results from the Ebro Observatory, on which Dr. Bauer had mainly relied, I employed data from two periods of years at Kew, determining a and b in all cases by least squares. Except in one case the value found for $100b/a$ was positive, but it was much below 0·8, and the values found for the correlation coefficients were too small to warrant the conclusion that a true sun-spot influence had been made out.

In his recent letter Dr. Bauer does not impugn the accuracy of my mathematical work. What he does is to employ instead of (1) a formula of the type

$$R = a' + b'S + c'T \quad . \quad . \quad . \quad . \quad (2)$$

where S is now the difference of the sun-spot number from its mean value, and T the time in years counted from the middle of the period. We may, I think, treat it as a mathematical certainty that the observational results must be expressible *exactly* by a formula of the type

$$R - a' - b'S = f(T).$$

What Dr. Bauer has found is that for one particular period of years $f(T) = c'T$ gives a good result at certain stations, notably Ebro and Eskdalemuir, which he considers good, and a less good result at other stations, Potsdam and Kew, which he considers inferior. He would no doubt get a still better result if he put

$$f(T) = c'T + d'T^2.$$

But is the goodness of fit in such a case any evidence of the real existence of a sun-spot influence? There might, for example, be an excellent fit with $b' = 0$.

There may admittedly be special conditions in which something is to be said for a formula of type (2). As I showed some years ago, the absolute value of potential gradient at Kew, and presumably elsewhere, is affected by the visibility (purity) of the atmosphere, potential falling as the visibility rises. If the purity of the atmosphere at a station improved at a uniform rate, potential gradient would naturally fall, and it might be a proper course to apply a corrective term $c'T$, with c' negative as found by Dr. Bauer at the Ebro, Eskdalemuir, and Kew. Again, if a station went on applying an invariable factor for the reduction to an infinite plane, while the factor was really altering owing to continuous deterioration of the insulation or other instrumental cause, a corrective term $c'T$ with c' negative might be justifiable if the rate of deterioration was constant.

The reasons assigned by Dr. Bauer, p. 203, for considering Kew an inferior station are the large size of c_2/c_1, the ratio of the amplitude of the 12-hour to the 24-hour Fourier wave, and the high mean value of potential. Now I can imagine another critic holding—and with equal reason—that a low value of c_2/c_1 and a low mean value of potential gradient are both symptoms of inferiority either in the site or in the apparatus. He might even suggest that the mean values at the Ebro, $86v/m$ in 1921 and $76v/m$ in 1922, are outstandingly low.

If a high mean potential gradient is a sign of

inferiority, the good character of Eskdalemuir seems difficult to explain, as the value there makes a much closer approach to the Kew than to the Ebro value, the latter being notably below what Dr. Bauer puts forward as the normal. Again, if a high value of c_2/c_1 is a sign of inferiority, is it not strange that c_2/c_1 is highest at Kew in summer when the potential gradient is lowest? Ebro and Eskdalemuir have a variable number of monthly quiet days, while at Kew with rare exceptions the number is uniform. Weather conditions usually reduce the number of quiet days used at Eskdalemuir below the Kew number 10. Thus *a priori* we should have expected Kew to be the station least affected by accidental irregularities. According to Dr. Bauer the sign of c' (his t) "may depend upon whether the sun-spot cycle . . . is below or above average development." Apparently he expects a revolutionary change from a steady fall to a steady rise and conversely! It is obvious that if a steady fall did go on at the Ebro at the rate obtained by Dr. Bauer we should before long have the potential gradient negative.

The fact that Dr. Bauer finds negative values for c' at all three stations, Ebro, Eskdalemuir and Kew, may possess some physical significance unrelated to sunspots. In my Physical Society paper I referred to volcanic dust as a possible natural agency influencing potential gradient over wide areas. Even the agency of man may influence a considerable area. Thus I had myself regarded the value for 1921 at Kew as exceptionally low, and attributed this at least in part to the abnormal purity of the English atmosphere brought about by the coal strike. At all events the mean value for 1922, unlike that at the Ebro, shows a substantial rise.

In view of Dr. Bauer's concluding remarks it may not be amiss to point out that the earth's atmosphere is generally believed to contain an equal and opposite charge to the earth's surface. Thus the total charge on the earth as a planet would seem to be *nil* whether a sun-spot influence exists or not.

Colour Vision and Colour Vision Theories.

IN his letter published in NATURE of August 25, Dr. Edridge-Green seems to admit the accuracy of the deductions from the trichromatic theory which I made in the issue of August 4. But, in making these, I used no other postulate than that of the fact of normal trichromasy. In the sense in which the word is used, trichromasy is now a qualitatively and quantitatively proved fact, although at the time of its first assertion it was in considerable part hypothetical. Strict logical development (which may be mathematical when necessary, since mathematics is merely symbolised logic from this point of view) leads directly to the explanation of certain phenomena which Dr. Edridge-Green had thought to be unexplainable on the basis of trichromasy. If the logical developments are sound, the conclusions are inevitable. But he brings forward three other facts which he still considers to be inexplicable on the theory.

First; a man, stated to be completely "red-blind," can recognise red as easily as a normal-sighted person. From the trichromatic point of view one might say, Why not? No doubt the term "red-blind" might preferably be avoided, seeing that it is a relic of the "hard-atom" stage of the theory; but the theory does not give the result that a dichromat of that type cannot distinguish red light from other lights. The notion that it must do so is a survival of ideas held under the restrictions of the early applications of the theory.

Second: 50 per cent. of the dangerously colour blind get through the wool test. Again, Why not? The theory would only use the fact, if granted, to aid in further elaboration of the details of the visual peculiarities.

Third: the theory is said to fail to explain the class of colour vision which Dr. Edridge-Green denotes as trichromatic, in which yellow is not recognised, the region of the spectrum occupied by yellow hues being called red-green. I cannot occupy space here in showing how this is directly predictable as a possibility on the trichromatic basis. I have discussed it, and other such cases, in my book on colour vision. Dr. Edridge-Green says that, in this case, the intersection of the dichromatic curves should be shifted towards the red on the trichromatic theory, and they are not so shifted. The statement is mistaken. There is no such compulsion on the theory.

The statements in Dr. Edridge-Green's last two sentences are in complete agreement with the theory. He says also that the theory is burdened with self-inconsistent subsidiary hypotheses. Actually the theory is based, and based alone, on two postulates; the qualitative postulate of trichromasy, and the quantitative postulate of the intensity law. All further development is straightforward, any definite constructive presumption being used in illustration only, and being clearly stated by Helmholtz to be quite inessential. In fact, he left the theory totally unburdened with fixed presumptions regarding structure and function. The fixation was to come later, probably by way of many supplemental theories consonant with it. All, including the views of Dr. Edridge-Green, may possibly help.

I would appeal to Dr. Edridge-Green not to pit his views against the trichromatic theory, but rather to consider wherein they may supplement it. Multichromasy higher than triple is without evidence. If he accepts Dr. Houston's work as the mathematical expression of his views, he thereby makes them trichromatic in the usual sense of the term. His views may supplement the theory on the side of functional physiology or psychology; they cannot refute it on the formal side.

August 25.

The Phosphate Deposit of Ocean Island.

ON p. 787 of NATURE of June 9, which has just reached me, a notice appears, under the heading of "Mineral Fertilizers," of my paper on "The Phosphate Deposit of Ocean Island" (Quart. Journ. Geol. Soc., vol. lxxix., p. 1, 1923.)

As this notice misinterprets certain of the statements made in the paper, I beg the courtesy of your space for the necessary corrections.

(1) One of the points emphasised in the paper is the gradual and uniform change which occurs in the composition of the deposit as one passes from perimeter to centre. This change is so regular that it can be expressed by a simple formula.

There is no normal 88 per cent. and no "level . . . where the phosphate sinks from its normal 88 to 79 per cent.," the change being gradual and without break from 79 to 92 per cent.

(2) The deposit cannot be truly described as having "a depth of fully fifty feet." As stated in the paper, it is sometimes as much as 80 feet thick, but usually less than 50 feet.

(3) The excess lime shown by analysis (*i.e.* the lime over and above that required for the phosphoric, carbonic, fluoric, and sulphuric acid radicals) varies

directly with the percentage of organic matter and inversely with the percentage of tricalcium phosphate. It is therefore more rational to assume that this lime is combined with the organic matter than to state (as has been done) that it is present as a compound of the type $x(Ca_3P_2O_8).y(CaO).zH_2O$.

Dahllite, $4Ca_3P_2O_8.2CaCO_3.H_2O$, is not mentioned in my paper. The idea of its occurrence is not rejected by me, however, as its presence is not in conflict with the chemical analyses, no excess lime (as defined above) being required for it.

That the calcium fluoride shown in the analyses (about 3 per cent.) is present combined as apatite to any considerable extent is unlikely, from the behaviour of the phosphate to reagents; the purer varieties of Ocean Island phosphate being, for example, almost completely soluble in cold, dilute hydrochloric acid.

Launcelot Owen.

Monteria,
Republic of Colombia,
South America, July 21.

I hope that no one who consults Mr. Owen's interesting paper will have been much troubled by misinterpretations on my part. The words "normal 88 per cent." are based on the analysis on p. 13 of the paper, which is said to be "representative" and gives 87·5 per cent. I hope, again, that no reader of my note would suppose that a level exists in the rock at which the phosphate-content drops suddenly to 79 per cent. I should have written "has sunk" for "sinks."

In suggesting on p. 13 of the paper, and in his letter, that lime is associated with the organic matter in the phosphate, Mr. Owen raises a question of wide importance. The special adsorptive influence of organic colloidal gels in soils is now well known, and Mr. Owen doubtless sets a good example in not presuming the presence of dahllite or any other mineral unless it can be recognised by specific characters in the mass. The rather delicate fibrous crystallisation of dahllite may be looked for. We must remember that A. Lacroix and other mineralogists recognise definite species of mineral "calcium carbo-phosphates." E. Blackwelder, on the other hand (*Amer. Journ. Sci.*, ser. 4, vol. 42, p. 294, 1916), regards the less definite collophane as the common product of the reaction between phosphoric acid and lime salts, especially calcium carbonate, in the presence of ammonia. Collophane, as Rogers shows, can associate fluorine with its colloidal substance, and may thus suggest the presence of apatite. In his researches on the chemistry of phosphatised reefs, Mr. Owen is opening up a very interesting petrological field.

The Writer of the Note.

The Metric Campaign.

In reviewing Drury's "World Metric Standardisation" (Nature, August 18, p. 234), the statement is made that "far less opposition has been raised to the adoption of the litre and gram than to the metre, which is very much more closely related to industrial processes than the units of mass and measure."

Perhaps the following will serve to indicate to metric campaigners why those who are directly interested in industrial processes are in such an impenetrable fog over the question.

A few days ago, in a retail tool shop in a provincial town, I was shown a narrow steel measure, in four folding sections, the total length being one foot, which was divided into 305 minor, and 30½ major and numbered divisions, the first two engraved thus:—1|meter|2, so that to the purchasers of such an instrument 30½ metres are represented as equivalent to 12 *inches, instead of* 100 *feet*! The stock included the carpenter's ordinary foot-rule, divided along one edge into inches and sixteenths of an inch, and the other into millimetres and 30½ (centi)metres. All the shopkeeper could say was that the scales were as supplied by the best makers, and must therefore be accepted as correct—the word *meter* had no other meaning than that the makers used it instead of saying the scale was French!

Four years ago, in a western London suburb, I had exactly the same experience, but if my memory serves me the makers were different. The shopkeeper informed me that in his two shops (one nearer the West End) he had already sold many hundreds of these scales.

From time to time the London and provincial Press report meetings at which there have been discussions on the great advantages of the metric system, but there the matter ends—apparently it is nobody's business, not even of the Board of Trade or the Board of Education, to take action which would ensure the circulation of correctly marked scales. All the wrongly engraved ones ought to be recalled, to have *centi-* engraved above *meter*.

Hy. Harries.

August 20.

Direction of β-rays Produced by Polarised X-rays.

In an abstract (Nature, July 7, p. 26) of a paper read recently before the Royal Society, Mr. C. T. R. Wilson discusses some results on β-ray ionisation tracks which he has obtained by his cloud method. Among other things he notes (1) "Partial polarisation of the primary beams is indicated by the direction of ejection of a number of the β-particles being in one plane—that containing the direction of the cathode rays in the X-ray tube," and (2) "Of the ordinary long-range tracks, the majority have a large forward component comparable with the lateral component."

During the past year the present writer, using a beam of scattered X-rays about 90 per cent. polarised (Wilson's primary beam was probably about 10 per cent. polarised), has obtained stereoscopic photographs of β-ray ionisation tracks by the cloud method. These photographs show that most of the β-particles are ejected in a direction nearly parallel to that of the electric force of the polarised beam of X-rays. There is, however, a variation on either side of this direction.

The photographs also support Wilson's conclusion that a large majority of the β-particles have a velocity component in the direction of propagation of the X-rays.

F. W. Bubb.

Washington University, Saint Louis,
July 30.

Proposed International Survey of the Sky.

I am informed by the director of the Office National Météorologique de France that, with the approval of Sir Napier Shaw, president of the International Commission for the Study of Clouds, the dates for taking the photographs of clouds have been postponed by one week. Photographs will be taken at the three specified hours from September 24 to October 1 inclusive. Volunteers are much needed to help in the work, and I shall be glad to send full instructions to those who will send me their names.

Gaseous Combustion at High Pressures.[1]

By Prof. W. A. BONE, F.R.S.

INTRODUCTION.

IN the course of the researches upon gaseous combustion which for many years past have been carried out in my laboratories, it became necessary to study the subject under much higher pressures than those heretofore employed. As this aspect of the work has recently assumed greater importance from the point of view of the mechanism of combustion than was at one time foreseen, an outline of it may be of interest. Before, however, explaining what our new observations have been, something should be said about the apparatus and methods employed for such work. For they must obviously differ from those used for experiments at atmospheric pressure, where the conditions are much less severe.

In the first place, the experiments must be carried out in specially designed bombs of forged steel capable of withstanding the sudden development of very high explosion pressures. Thus, in our recent experiments, the initial pressure at which the combustible mixtures were fired ranged up to 100 atmospheres; and the resulting pressures, which were developed in a small fraction of a second, were anything up to ten times as great. Hence the method of measuring and recording the pressures must be capable of following accurately, and with the least possible lag, a rise of pressure of from (say) 100 to 1000 atmospheres occurring within $\frac{1}{200}$th of a second. For this purpose we have employed a recording manometer of the form designed by Sir J. E. Petavel, which is a most efficient appliance for high-pressure explosion work.[2]

The photographic pressure-time records obtained in our experiments show (1) the rate at which the potential energy of the explosive mixture fired is transferred into kinetic (*i.e.* pressure or temperature) energy of the products; (2) the ratio of the maximum pressure attained on explosion to the initial pressure at which the mixture was fired—usually denoted as P_m/P_i; and (3) the rate of the subsequent cooling. From a study of these and other features of the records we are able to draw conclusions as to certain fundamental aspects of the combustion process itself.

SOME FEATURES OF THE COMBUSTION OF HYDROGEN AND OF CARBON MONOXIDE IN AIR.

As an example of the potentiality of high-pressure explosion research to reveal and elucidate new factors in gaseous combustion, I propose to deal mainly with the cases of hydrogen and carbon monoxide. For although at first they may seem to be of the simplest type, yet they present features of extraordinary interest and complexity which for many years past chemists have vainly tried to explain. Even engineers, who study internal combustion problems in their own way, without troubling themselves overmuch with the mechanism of the chemical changes involved, are seeking light upon what is termed the "suppression of heat" in such explosions. Indeed our present ignorance about these matters shows how far we are from really understanding the elements of gaseous combustion, and the need there is of much further fundamental research thereon.

From a chemical point of view there has always been something enigmatical about the very different behaviours of the two simplest combustible gases, hydrogen and carbon monoxide, when burning in air. For although their volumetric heats of combustion (assuming the initial and final temperatures being both about 15° C.) and the proportion by volume in which each of them combines with oxygen are the same, namely:

$$\left.\begin{array}{l} 2H_2 + O_2 = 2H_2O \quad \ldots \quad 68{\cdot}4 \\ 2CO + O_2 = 2CO_2 \quad \ldots \quad 68{\cdot}0 \end{array}\right\} \text{K.C.U. per gram-molecule,}$$

yet in many respects their modes of combustion in air present a striking contrast.

Thus, for example, (1) the appearance of a flame of hydrogen in air is very different from the lambent blue flame of carbon monoxide burning at the same orifice and under the same pressure; (2) hydrogen-air mixtures have lower ignition temperatures, and, under similar physical conditions, propagate flame much faster than the corresponding carbon monoxide-air mixtures; (3) the presence of even a minute quantity of steam greatly assists, if it is not absolutely essential to, the oxidation of carbon monoxide in flames, even when detonation is set up—thus a flame of the dry gas is easily extinguished on being introduced into a jar of air that has been previously dried over strong sulphuric acid; (4) a flame of carbon monoxide burning in air loses by radiation nearly 2·4 times as much energy as a hydrogen flame of the same size; also (5) the two radiations have their own characteristic wave-lengths—namely, 2·8 μ from a carbon monoxide-air flame and 4·4 μ from a hydrogen-air flame—which have been attributed to vibrational conditions in incipiently formed CO_2 and HO_2 molecules respectively, or, as I prefer to say, to the formation *at the moment of combustion* of intensely vibrating carbon monoxide-oxygen and hydrogen-oxygen complexes, which ultimately give rise to carbon dioxide and steam molecules respectively.

To summarise: carbon monoxide burns in air more slowly and with a more highly radiating flame than does hydrogen; also apparently the presence of some steam or other hydrogen-containing substance is necessary for its combustion. Precisely how steam accelerates or determines the combustion of carbon monoxide (and only a minute quantity suffices) has up to now never been completely explained; but chemists are generally agreed that carbon monoxide molecules are particularly inert towards oxygen molecules in flames. Indeed I think there are grounds for believing that in ordinary flames carbon monoxide cannot react with undissociated oxygen molecules, but that it requires the presence of either :O atoms or "activated steam" :OH_2 molecules.

[1] From a discourse delivered at the Royal Institution on Friday, May 11.
[2] A full description of the bomb and accessory appliances will be found in Phil. Trans. Roy. Soc., A 215 (1915), pp. 275-318.

HIGH-PRESSURE EXPERIMENTS.

Bearing the foregoing considerations in mind, let us now see what new light has been shed on the problem as the result of high-pressure combustion research. Here it should be pointed out that, inasmuch as the chief difference between the condition of high- and low-pressure experiments lies in the absolute concentration of the interacting molecules, it may be expected that factors the operation of which chiefly depends on such concentration will become more dominant as the pressure arises. Indeed, the value of high-pressure work lies in the fact that it tends to show up and accentuate the operation of factors the influence of which may be either masked or overlooked at ordinary pressures.

One of the first things disclosed by our experiments was the absence of any direct relation between the rate at which the potential energy of an explosive mixture is transferred on explosion to its products as sensible heat (pressure) and the magnitude of the chemical affinity between its combining constituents. Thus, for example, the time required for the attainment of maximum pressure on exploding at 50 atmospheres a methane-air mixture ($CH_4+O_2+4N_2$), in which the combustible gas and oxygen are present in equimolecular proportions (*i.e.* corresponding to the primary chemical interaction in the flame), was many times longer than that required in the case of the corresponding hydrogen-air mixture ($2H_2+O_2+4N_2$), notwithstanding the fact that the affinity of methane is at least twenty, and possibly as many as thirty, times as great as that of hydrogen for oxygen in flames. In other words, the avidity with which a combustible gas seizes upon oxygen in flame combustion is not necessarily the factor which mainly determines the rate at which the potential energy of the mixture is transferred into kinetic energy of its products.

Later experiments have chiefly dealt with the explosion usually at an initial pressure of 50 atmospheres of what may be termed isothermic mixtures of either carbon monoxide or hydrogen with sufficient oxygen for complete combustion *plus* some variable diluent developing as nearly as may be the same amount of energy on combustion. I will now endeavour to explain their significance.

THE CONTRAST BETWEEN CARBON MONOXIDE-AIR AND HYDROGEN-AIR PRESSURE CURVES.

We may appropriately begin with a consideration of two typical pressure-time records (Fig. 1) obtained when normal carbon monoxide-air and hydrogen-air mixtures ($2CO+O_2+4N_2$ and $2H_2+O_2+4N_2$) were respectively fired in the bomb at an initial pressure of 50 atmospheres.

Now, although these two mixtures developed as nearly as may be the same total amount of energy on explosion, there was a striking contrast between the character of the pressure-time curves obtained. For whereas in the typical hydrogen-air curve the pressure rose with extreme rapidity (actually in 0·005 second) to its maximum (about 400 atmospheres), and almost immediately thereafter began to fall and assume the character of a simple cooling curve, in the corresponding carbon monoxide curve the pressure rose much more slowly and only attained a maximum (about 410 atmospheres) after 0·18 second, after which it was maintained almost at its maximum for a considerable time interval. The comparative slowness with which pressure energy is developed in such a carbon monoxide-air explosion, together with a considerable exothermic effect after the maximum pressure had been reached, were indeed very remarkable and significant features of our experiments. At first we were inclined to attribute them to the supposed "slow-burning" property of carbon monoxide as compared with the "quick-burning" of hydrogen; but further experiments revealed the operation of another totally unexpected factor—namely, the presence of nitrogen, which, as we discovered later, is not inert but acts as an "energy-absorber" in the combustion of carbon monoxide at such pressures.

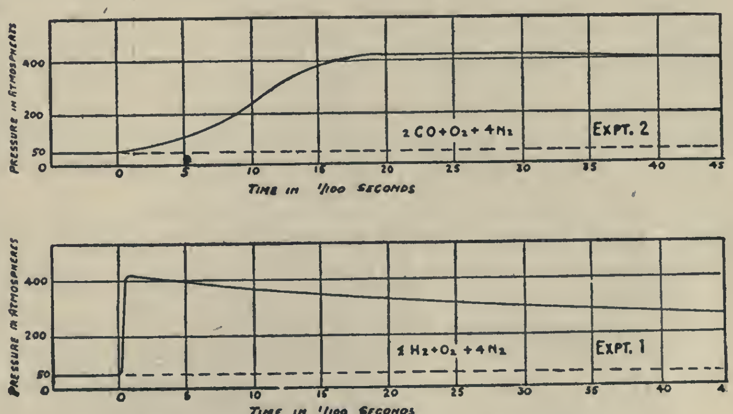

FIG. 1.—Pressure-time records for the explosion of carbon monoxide-air and hydrogen-air mixtures.

EFFECT OF ADDITION OF HYDROGEN UPON THE CARBON MONOXIDE-AIR CURVE AND UPON A CARBON MONOXIDE FLAME BURNING IN AIR.

It was next discovered that the replacement, even in very small proportions, of carbon monoxide by its equivalent of hydrogen in the aforesaid normal carbon monoxide-air mixture had a disproportionately large influence in accelerating the rise of pressure on explosion. This remarkable result, which is of considerable theoretical import, was dealt with at length in a paper published two years ago by the late W. A. Haward and myself in the Proceedings of the Royal Society.[3] Indeed at first sight it seemed as if the hydrogen had imposed its own character upon the whole course of the carbon monoxide combustion, even when the combustible part of the mixture exploded contained only one part of hydrogen to twenty-three parts of carbon monoxide by volume.

In this connexion it may be mentioned that the addition of a moderate amount of hydrogen to carbon monoxide burning in air at ordinary pressure has a considerable effect upon the character and spectrum of

[3] Proc. Roy. Soc., A. 100 (1921), pp. 67-84; see also a further paper in the current (August) number of the Journal of the Chemical Society.

the flame, a circumstance which seems to be of some significance in relation to the mechanism of carbon monoxide combustion. In conjunction with Prof. A. Fowler, of the Imperial College, South Kensington, we are now investigating it more closely with the view of finding out its meaning. But the facts known warrant us in concluding that the addition of a comparatively small proportion of hydrogen has a peculiar influence upon the combustion of carbon monoxide, whether at high pressures (as in our bomb experiment) or in flame combustion at ordinary pressures.

THE MECHANISM OF THE COMBUSTION OF CARBON MONOXIDE.

To explain the peculiar influence of hydrogen or steam upon the combustion of carbon monoxide, I think it must be supposed that oxygen and carbon monoxide molecules are mutually inert in flames, and that before the carbon monoxide can be oxidised the O_2 molecules must be resolved either into O atoms or into "activated" steam. This precedent condition can be brought about by the presence of hydrogen (or maybe steam) in the mixture undergoing combustion. For, according to my present view, an undissociated O_2 molecule on being heated in the flame has its "residual affinities" sufficiently stimulated to enable it to seize upon two hydrogen molecules, forming initially an unstable vibratory complex H_4O_2. Such a complex, being in an intensely vibratory condition, would instantly break down (1) *partly* into two molecules of steam, also in a vibratory (and therefore "activated") condition, and (2) partly also into two : O atoms and two H_2 molecules, thus :

$$100\left(\begin{array}{c} O\langle^{H}_{H} \\ \| \\ O\langle^{H}_{H} \end{array}\right) \begin{array}{c}\text{would give rise to}\\ \text{(simultaneously)}\end{array} \left\{\begin{array}{l} (1)\ n \times 2 : O\langle^{H}_{H} \\ (2)\ (100-n)\ (2O : +2H_2). \end{array}\right.$$

The ratio $n/(100-n)$ would obviously depend upon both temperature and environment. The higher the temperature and the less hydrogen in the environment the less the magnitude of n. But in all conditions the hydrogen in a combustible mixture containing also carbon monoxide functions as a resolver of O_2 molecules simultaneously into (1) "activated" steam and (2) : O atoms. Thus it is suggested that the primary function of hydrogen as a promoter of the combustion of carbon monoxide is to resolve the O_2 molecules (inert towards carbon monoxide) into : O atoms and "activated" OH_2 (reactive towards carbon monoxide), itself being continuously regenerated in the process, as is shown in Fig. 2.

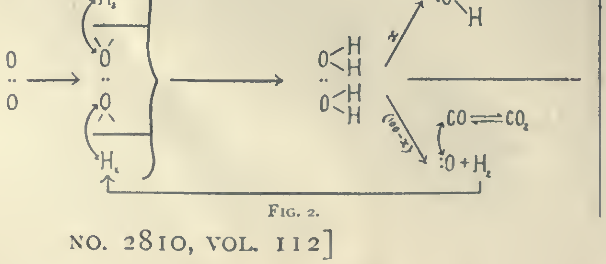

FIG. 2.

It may be observed that this view is similar to the one advanced forty years ago by Prof. H. B. Dixon to explain his discovery of the mutual inertness of dry carbon monoxide and oxygen in flames, but modified in one particular so as to make it more applicable to the further facts now known. He supposed that carbon monoxide is oxidised by OH_2 (but not by O_2) molecules in flames, the resulting hydrogen being immediately burnt to steam, which was thus continuously regenerated, as follows :

$$\left\{\begin{array}{l} (a)\ CO + OH_2 = CO_2 + H_2 \\ (b)\ 2H_2 + O_2 = 2H_2O \end{array}\right\}.$$

If, however, only such interactions (and no others) occur, it is difficult to understand why the colour and spectrum of a flame of pure (moist) carbon monoxide are so unlike those of hydrogen burning in air. The characteristic spectrum of a carbon monoxide flame, which extends far into the ultra-violet, would surely seem to be due to the formation in it of some CO_2 molecules in a more highly vibratory state than would be likely to arise merely by interactions of CO and OH_2 molecules. The difficulty in question is obviated, and also other facts would be better explained, by supposing (as I do) that an unstable vibratory H_4O_2 complex, primarily formed by the interaction of O_2 and H_2 molecules, decomposes in each of two ways yielding : OH_2 and : O atoms, both of which are capable of oxidising carbon monoxide.

THE ENERGY-ABSORBING FUNCTION AND ACTIVATION OF NITROGEN IN THE COMBUSTION OF CARBON MONOXIDE.

It next occurred to us to try the effects of progressively replacing the nitrogen of a normal carbon monoxide $(2CO + O_2 + 4N_2)$ mixture by molecular equivalents of other gases, *e.g.* oxygen, carbon monoxide, or argon. The first two of these gases are diatomic, and would have much the same densities and heat capacities as the nitrogen which they replaced ; and although they might be expected to exert some "chemical mass" influence upon the combustion, yet in all other respects they would act as "diluents." In argon we had an absolutely inert monatomic gas of higher density, but smaller volumetric heat capacity, than nitrogen, and incapable of any internal vibrational energy. It would therefore presumably be incapable of exerting any effect upon the explosion other than that of merely sharing, by molecular collisions, in the increased kinetic energy acquired by the system as the result of the combustion.

It may be observed that while the said replacement of the nitrogen by the other gases would not affect in any way the total energy liberated on explosion, yet the experiments showed that it affected somewhat the proportion of the energy recorded by the gauge as pressure (temperature) at the instant of maximum pressure, and still more so the rapidity with which the said pressure energy was developed. The most important experimental results from this point of view are summarised in the following table, and illustrated by the set of pressure-time curves reproduced in Fig. 3. Here it may be pointed out that the most essential

data which must be established in such experiments are the following:

P_i = the initial pressure in atmospheres at which each mixture is fired.

P_m = the maximum pressure in atmospheres recorded in the explosion.

t_m = the time in seconds required for the attainment of the maximum pressure after ignition.

Σ = the thermal equivalent in K.C.U. of the energy liberated during the explosion.

Also the percentage amount by which P_m falls during (say) 0·5 sec. after t_m.

Mixture exploded.	Σ.	P_i.	t_m.	P_m.	P_m/P_i.	Per cent. Fall in Pressure in 0·5 sec. after t_m.
$2CO+O_2+4N_2$	10·2	50	0·190	409	8·18	11·6
$2CO+O_2+4O_2$	10·0	50	0·005	460	9·20	33·33
$2CO+O_2+4CO$	10·4	50	0·010	450	9·00	34·3
$2CO+O_2+4Ar$	10·2	50	0·025	510	10·20	26·4

These and other similar results led very decidedly to the conclusion that the nitrogen present in the normal carbon monoxide-air mixture had been exerting a specific influence on the whole course of events, which was manifested in a three-fold effect upon the pressure curves—namely, (1) a marked retardation of the rate of attainment of maximum pressure, (2) a lowering of the maximum pressure, and (3) a considerable retardation of the subsequent cooling. For whenever such nitrogen was wholly replaced by its molecular equivalent of any one of the other three gases, the development of pressure became nearly as rapid as in the explosion of a normal hydrogen-air mixture under like conditions. Moreover, comparative analyses of the pressure-time records obtained during the experiments in question have shown that, when nitrogen was present, much less kinetic (pressure) energy was absorbed up to the attainment of maximum pressure than was subsequently liberated during the cooling period. This remarkable circumstance shows that a considerable part of the radiation emitted by the burning carbon monoxide (which otherwise would have been absorbed by the walls of the explosion vessel) was intercepted by the nitrogen present. Part of the nitrogen so irradiated would then, in favourable circumstances, be oxidised to nitric oxide, thereby absorbing part of the kinetic energy developed by the explosion and consequently reducing the maximum pressure attained. Finally, the radiant energy so absorbed by the nitrogen, *plus* part of the kinetic energy (if any) absorbed in forming nitric oxide during the combustion, was liberated as kinetic energy during the cooling period, so delaying the cooling. Thus it was manifest that under our experimental conditions nitrogen has the power of absorbing part of the radiant energy developed by the combustion of carbon monoxide, and of slowly giving it out again in a kinetic form during the subsequent cooling period. In other words, nitrogen is not inert, but acts as an "energy absorbing" spring in such explosions. Indeed the results set forth in the foregoing table can scarcely be explained on any other supposition.

Another important conclusion arising out of these experiments is that when nitrogen so absorbs radiant energy developed during a carbon monoxide-air ($2CO + O_2 + 4N_2$) explosion under such conditions, it becomes chemically "activated," and capable of combining much more readily with oxygen than does nitrogen which has merely been raised to a correspondingly high temperature in a similar hydrogen-air ($2H_2 + O_2 + 4N_2$) explosion. Indeed, when the bomb was rinsed out with distilled water after one of our hydrogen-air explosions at an initial pressure of 50 atmospheres, no more than a faint trace of nitric acid could be detected on applying the diphenylamine test to the washings; whereas, in the case of the corresponding carbon monoxide-air explosions, a similar test always showed a considerable formation of nitric acid.

It would seem as though the nitrogen molecule is able to absorb the particular quality of radiation emitted as the result of the interactions of CO and :O during a carbon monoxide-air explosion, which is different from that emitted during a hydrogen-air explosion. In other words, it seems as though there is

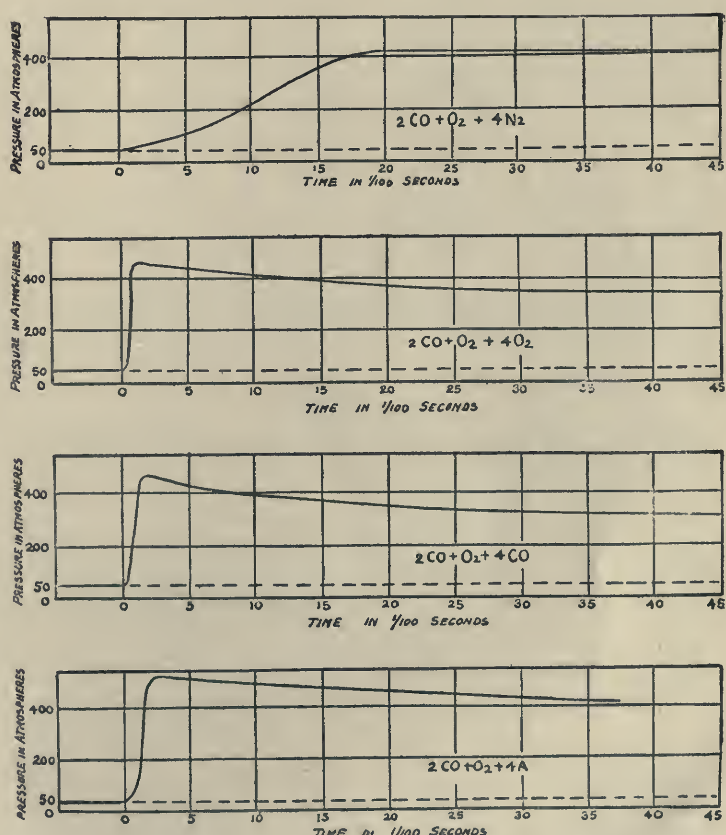

FIG. 3.—Pressure-time records for the combustion of carbon monoxide using different diluents.

some constitutional correspondence between CO and N_2 molecules (the densities of which are identical) whereby the vibrational energy (radiation) emitted when the one burns is of such a quality as can be readily absorbed by the other, the two thus acting in resonance. The radiant energy so absorbed during the explosion presumably would not affect the maximum pressure attained, except in so far as the conditions permitted of any secondary oxidation of the "activated" nitrogen to nitric oxide during the actual combustion period; but radiant energy so absorbed would be liberated in a kinetic form during the subsequent cooling period, as the "activated" nitrogen slowly reverted to the ordinary form. Analyses of the pressure-time records obtained have entirely confirmed this supposition.

The following graphs (Fig. 4) illustrate the strength of the evidence obtained up to this point as to the activation of the nitrogen during a carbon monoxide-air explosion at high pressures. They show the rates of cooling (expressed as pressure fall in atmospheres per second) of the gaseous systems immediately after the attainment of maximum pressure, when each of the four mixtures, $2CO+O_2+4N_2$, $2CO+O_2+4O_2$, $2CO+O_2+4Ar$, and $2H_2+O_2+4N_2$, were exploded in the bomb at an initial pressure of 50 atmospheres.

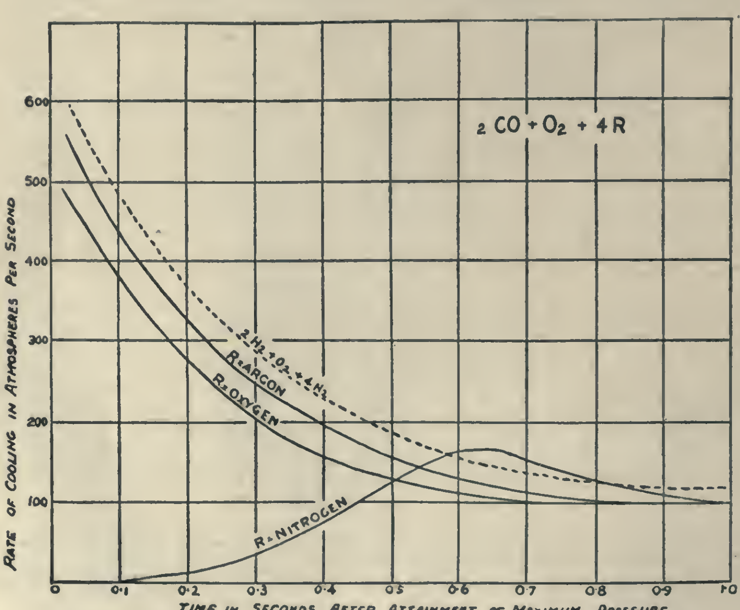

FIG. 4.—Rate of cooling after combustion of carbon monoxide using various diluents.

It will be seen that, except in the case of the carbon monoxide-air mixture, the cooling was perfectly regular, and presented no abnormal features whatever. In the case of the $2CO+O_2+4N_2$ mixture, however, there was no cooling at all during the 0·1 sec. after the attainment of the maximum pressure; and it was not until the lapse of the 0·6 sec. thereafter that anything like a normal rate of cooling was established. Attention is specially directed to the striking contrast between the perfect normality of the first 0·6 sec. of the cooling period in the case of the hydrogen-air ($2H_2+O_2+4N_2$) mixture, and its complete abnormality in the case of the corresponding carbon monoxide-air mixture. This circumstance, combined with the perfect normality of the cooling in the case of the $2CO+O_2+4Ar$ mixture, can scarcely be explained except on the assumption that the nitrogen functions differently in a hydrogen-air explosion, where it acts as an inert diluent only, from what it does in a carbon monoxide-air explosion, where in addition to its ordinary diluent action it has a peculiar energy-"absorbing" effect, whereby it becomes chemically "activated." On such an assumption the meaning of the $2CO+O_2+4N_2$ cooling curve is that the radiant energy which had been absorbed by the N_2 molecule during the previous combustion period was being slowly evolved in a kinetic form far into the subsequent cooling period, the "activated" nitrogen not having entirely reverted to its normal condition until at least 0·6 sec. after the end of the combustion period.

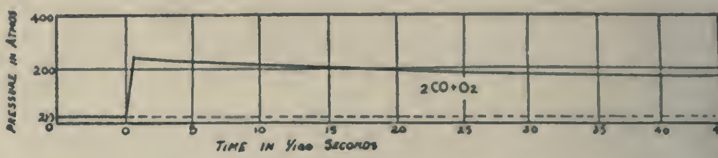

FIG. 5.—Pressure-time record of carbon monoxide-oxygen explosion.

EXPERIMENTS WITH SOME ISOTHERMIC MIXTURES.

Much confirmatory evidence of the radiant energy-absorbing function and consequent "activation" of nitrogen in the combustion of carbon monoxide at high initial pressures has been obtained as the result of experiments in which mixtures of carbon monoxide and oxygen in their combining proportions, diluted with successive molecular proportions (2, 4, or 6) of the four diluents, argon, carbon monoxide, oxygen, or nitrogen, were fired at such initial pressures as would always result in the liberation of the same total energy (about 10 K.C.U.) during the subsequent explosion. For details of these experiments the reader is referred to the memoir recently published in conjunction with my co-workers (D. M. Newitt and D. T. A. Townend) in the Proceedings of the Royal Society, A. 103, pp. 205-232. There is, however, a significant feature about the pressure-time records (Fig. 5) obtained when an undiluted $2CO+O_2$ mixture was fired in our bomb at an initial pressure of 21·4 atmospheres, to which reference should here be made, because of its bearing on the theory of CO-combustion.

It will be seen that the maximum pressure (245 atmospheres) was developed in 0·005 sec., after which the cooling period immediately set in; the pressure fall during the next 0·5 sec. being 66 atmospheres, or about 27 per cent. of the maximum. It is evident that an exceedingly high temperature was momentarily attained in this experiment; indeed, assuming that the

"chemical contraction" involved in the passage from $2CO+O_2$ (3 vols.) to $2CO_2$ (2 vols.) was substantially completed at the instant of maximum pressure, the temperature at that instant would have been of the order of 5000° C. In any case the experiment finally disposes of the supposition that carbon monoxide is inherently a "slow-burning" gas. Moreover, the whole character of the pressure-time curve seems inconsistent with the idea, which has sometimes been put forward, that the maximum pressure attained on explosion is materially affected by the dissociation of carbon dioxide; indeed, there was no sign of any "after burning" or heat evolution after the maximum pressure had been attained.

Concluding Remarks.

The energy of a gaseous system such as we have considered is of course comprised partly of translational motions of its molecules as a whole, and partly of motions of some kind internal to these molecules. The former causes pressure (temperature), but the latter (which according to circumstances may be partly rotational and partly vibrational) produces no external physical effect other than radiation, which originates in high-frequency vibrations within the molecule.

Now in each of our experiments a definite amount of energy (thermally equivalent to about 10 K.C.U.) was liberated by the union of carbon monoxide and oxygen in the bomb. Presumably the greater part of this would appear as increased kinetic energy of the products as a whole (*i.e.* as pressure). The lesser part of the energy liberated in such explosions would manifest itself as "radiation" of wave-lengths characteristic of burning carbon monoxide; *i.e.* of incipiently forming carbon dioxide molecules in a highly vibrating state such as would result from CO and : O collisions. Now when nitrogen is present as a diluent it is able to intercept part of the "radiation" whereby it acquires energy of a vibrational kind, which may be intense enough even to dissociate the two atoms of its molecule, or in any case to "activate" it chemically. Such an absorption of radiant energy presumably would not affect the ratios P_m/P_i, except in so far as any part of the nitrogen primarily "activated" successfully competed with the burning carbon monoxide for the available oxygen, and thus became oxidised to nitric oxide during the combustion period. Indeed further experiments (now proceeding) have shown that such nitrogen "activation" is materially influenced by the initial pressure at which the explosive mixtures are fired; but this is an aspect of the matter which time does not permit me to develop.

There is of course nothing new in the idea of an "active" form of nitrogen, for ten years ago the Hon. R. J. Strutt (now Lord Rayleigh) discoursed upon it, and showed how ordinary nitrogen is chemically "activated" when subjected at low pressures to a Leyden jar discharge, whereby it glows and acquires the power of combining with various substances towards which it is normally inert. Such "active" nitrogen was found to be strongly endothermic, and Strutt favoured the view that it consists of dissociated nitrogen atoms, and recombination to form ordinary nitrogen caused the characteristic afterglow.[4]

Another view of the "activation" of nitrogen has been suggested which does not necessitate the complete dissociation of nitrogen molecules. According to Langmuir's statical representation of atomic constitution, there is a great similarity between the configuration of carbon monoxide and nitrogen molecules in the ordinary state, a circumstance to which he has directed special attention. He considers that both molecules are capable of existing in two forms, in one of which (the ordinary and more inert form) the two positive nuclei are both symmetrically located within one and the same outermost shell of eight electrons, whereas in the "active" form they are situated each within one of two separate shells, which have four electrons in common. According to this view not only would the "activation" of each gas be brought about by a reversible transformation from the one configuration into the other, as is shown in Fig. 6, but also an inert nitrogen configuration should be capable of being activated through resonance with a carbon monoxide molecule of similar configuration undergoing combustion.[5]

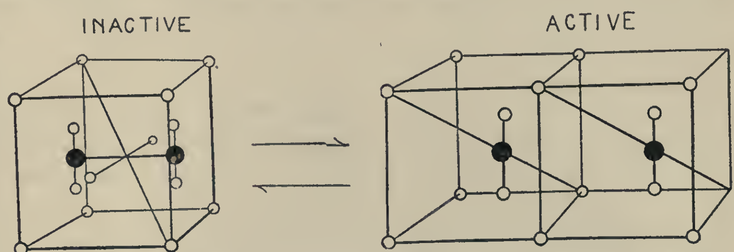

FIG. 6.—Models illustrating the reversible transformation of active nitrogen or carbon monoxide into the inactive form.

It is interesting now to recall the following passage from one of Faraday's letters to Schönbein, which was quoted by the present Lord Rayleigh, when lecturing on "Active Nitrogen" ten years ago. "What of nitrogen? Is not its apparent quiet simplicity of action all a sham? Not a sham, indeed, but still not the only state in which it can exist. If the compounds which a body can form show something of the state and powers it may have when isolated, then what should nitrogen be in its separate state?" Perhaps the behaviour of nitrogen in our high-pressure carbon monoxide-air explosions will help in realising more fully the deep significance of Faraday's words.

In the earlier part of my discourse I directed attention to the peculiar influence of a small addition of hydrogen to a carbon monoxide-air mixture undergoing combustion whether at atmospheric pressure or when exploded at high pressures in the bomb. We have also found that a similar small addition of hydrogen to a normal carbon monoxide-air mixture

[4] Proc. Roy. Inst., vol. xx. part 3 (1914), pp. 656-61.

[5] It may be noted that support is given to the idea of a similarity between the electronic configurations of nitrogen and carbon monoxide, and their capability of acting in resonance during explosions at high pressures, by a paper appearing in the Proceedings of the Physico-Mathematical Society of Japan for April last (*vide* NATURE, June 23, p. 859). For if the electronic configurations of the two gases are similar, their band spectra should be in close agreement; and this is shown to be the case. The author, however, remarks that the specific heat ratios of the two gases are incompatible with Langmuir's assumption of the two nuclei being in the same cube; and he suggests an alternative model, in which two cubes are joined at an edge.

undergoing combustion at high pressures is prejudicial to the "activation" of nitrogen. This is a point of considerable theoretical as well as practical interest; and it harmonises with the views which I have put forward respecting the mechanism of carbon monoxide combustion.

Leaving the many theoretical issues raised by our experiments to be settled by a further appeal to facts as the investigation proceeds, I perhaps may be permitted to indicate in conclusion one or two directions in which, if followed up with adequate means and resources, the work might lead to results of further interest.

In the first place, we have already in some of our experiments attained extraordinarily high temperatures; and we could go even higher were it not for the fact that we are approaching the safety limits of the bomb. If funds were forthcoming for the construction of a new bomb, with the necessary accessories, to enable us to work at still higher initial pressures than we have hitherto employed, we should be able to study the effects of subjecting small quantities of diluent gases to the combined influence of exceedingly high temperatures and intensive radiation. This is an aspect of the research which we are hoping it may be possible for us to pursue in the interests of science.

It is also obvious that our results may have considerable bearing upon the problem of nitrogen fixation. For, having proved that nitrogen can be activated by the combustion of carbon monoxide at high pressures, especially when hydrogen is so far as possible excluded from the system, we have in blast-furnace gas an almost unlimited supply of just the right kind of raw material from which nitric acid could undoubtedly be easily produced under the conditions indicated by our experiment. In view of the national importance of nitrogen fixation we hope these possibilities will be thoroughly explored at home, and not left entirely to foreign organisations, which will probably not be slow to seize upon them. High-pressure combustion work is opening up new possibilities of extending our knowledge, and however much chemical research may have taught us concerning flame and combustion since the time of Davy, there remains a vast amount still to be learned.

Current Topics and Events.

THE terrible calamity in Japan caused by an earthquake on Saturday last, September 1, arouses the most profound sympathy in the scientific world, in which every one has the highest regard for the brilliant achievements of the Japanese. It is reported that the cities of Yokohama and Tokyo, including the Imperial University buildings, have practically been destroyed and that as many as 300,000 persons have lost their lives. The catastrophe is therefore one of the greatest ever recorded, and Japan will need all the help which other nations can give in order to recover from it. The chief shocks occurred about noon on Saturday and were recorded at 4h. 11m. 18s. on Saturday morning on Mr. J. J. Shaw's seismograph at West Bromwich, Birmingham, as well as at other seismological stations throughout the world. The earthquake was preceded by a typhoon; and it will be remembered that the Messina–Reggio earthquake at the end of 1908, when 77,000 lives were lost, was similarly preceded by torrential rain. It is reported that the Osaka Observatory places the seismic centre in the Izu Peninsula. When, in 1906, an earthquake wrecked a great part of the city of San Francisco, the terrible fire which broke out immediately afterwards completed the destruction, and this appears to have been the course of events at Tokyo and Yokohama. As is usual, high sea-waves, often incorrectly called "tidal waves," have flooded low-lying land and thereby added to the destruction and casualties. Most Japanese earthquakes originate in the great trough of the ocean floor, nearly $5\frac{1}{2}$ miles deep, known as the Tuscarora Deep, between the Kurile Islands and the coast of Japan. This was the place of origin in 1896 when the coast of Japan was devastated by three great waves, the largest about 50 feet in height, which caused the destruction of 20,000 lives in a few minutes. The Messina–Reggio earthquake similarly originated beneath the sea and a destructive sea-wave rose to a height of 25 feet and swept over the coasts on both sides of Messina Strait. Japan has suffered grievously from earthquakes and effects caused by them, but the catastrophe of Saturday last seems to have been the worst that it has experienced, and the Japanese people will need great fortitude in order to face the future with the confidence in which they have met other trials in the past.

SIR ARTHUR EVANS has published in the *Times* of August 28 and 29 an account of his past season's excavations at Knossos, which have produced some remarkable results. In particular, a wonderful series of frescoes was recovered from a town house, belonging to the beginning of the Late Minoan age, which was found at a depth of about five metres in an unexcavated strip of ground running up almost to the western border of the Palace. The frescoes had been torn from the walls of upper rooms in the house and lay heaped together in a very fragile state. The principal elements of three or four whole scenes, besides a multitude of detailed features, have been reconstituted. Taken as a whole they are said to afford a unique illustration of the painter's art of the golden age of Minoan Crete at approximately 1600 B.C. The variety of naturalistic detail, which is described as going beyond anything yet brought to light among Minoan remains, includes marine growths, birds, and many flowering plants, some of which can be identified. Monkeys of the genus Cercopithecus, which are not found nearer than the Sudan, and a group of three warriors, of which two are negro mercenaries, point to close African connexions. Some of the painted fragments are partly filled with Minoan writing. The abutment on the Palace of the important prehistoric main road from the south has been established, and Sir Arthur Evans

has found traces of it extending to Phaestos and thence to the havens of the African Sea. It thus brought Knossos into direct connexion with the Nile valley, and explains the intimate relations with Egypt, going back to the earliest dynastic age and beyond, which are recorded in the series of Egyptian relics found in the excavations on this site.

A GALE of unusual severity for the time of year was experienced over England during the latter part of Wednesday, August 29, and the early part of Thursday, August 30. At places in the south-west of England and at Scilly, the strength of the storm reached the force of a "whole gale," the anemometers registering a velocity of 60 miles an hour, while elsewhere on the south and east coasts and in the central parts of England the force of a "strong gale" was experienced, the anemometers registering a velocity of 50 miles an hour. The intensity of the gale was very prolonged, the greatest strength of the storm continuing in many places for six or eight hours. On Tuesday evening, August 28, the centre of the storm was located about 500 miles west-south-west of Ireland and was approaching the British Isles at the rate of thirty-five miles an hour. The centre of the storm passed over Ross-on-Wye on Wednesday evening, when the barometer read 29·17 in., and it continued in a north-easterly track across England, reaching southern Norway by Thursday evening. A noteworthy feature of the storm was the rapid movement or progress of the storm area, which maintained a rate of thirty-five miles an hour for a distance of about 1500 miles from the Atlantic to the North Sea. Heavy rain accompanied the storm, falling most in the advance segment; the amount measured exceeded an inch in the south of Ireland, and at places on the south-west and west coasts of England. Little rain fell in the rear of the disturbance, the weather rapidly clearing as the barometer rose, and brilliant sunshine was fairly general, ten to eleven hours being registered on Thursday, August 30, over England, except in the north and north-west.

THE sixty-eighth annual international exhibition of the Royal Photographic Society will be opened at 35 Russell Square, on Saturday, September 15, at 3 P.M., by the Rt. Hon. Lord Riddell. The exhibition will be open free to the public on September 17-October 27.

WE much regret to announce the death, at fifty-four years of age, of Sir Henry Hayden, F.R.S., formerly director of the Geological Survey of India, in an accident while descending the Finsteraarhorn on August 13; also of Mr. E. K. Muspratt, vice-chairman of the United Alkali Company, president of the Society of Chemical Industry in 1885 and member of the council of the University of Liverpool, on September 1, aged eighty-nine.

THE London Press recently reported the fall of a meteorite during a storm at Immingham, in North Lincolnshire, and stated that it had been secured by the Vicar. The matter has been investigated by Mr. T. Sheppard, of the Municipal Museum, Hull, who finds that the alleged meteorite is a piece of slag from the local ironworks, though it certainly appears to have been fused by having been struck by lightning, which will account for an eye-witness's statement that it made a hissing noise in the water and that steam rose from it.

UNDER the auspices of the National Union of Scientific Workers a meeting is to be held in the Hartley Botanical Laboratories, University of Liverpool, on Friday, September 14, at 5.30 P.M., to which all members of the British Association are invited. A discussion on the relation of "Science and Industry" will be opened by Prof. J. M. Thompson: Mr. J. Sandeman Allen, chairman of the Liverpool Chamber of Commerce, is to preside. It is hoped that a large attendance of local business men will be secured, in order that their interest in the application of science and the claims of men of science for their sympathetic interest and support may be further stimulated.

THE Vancouver correspondent of the *Times* states that a member of the relief party sent in search of the Canadian expedition to Wrangel Island has returned to Nome, Alaska, bringing with him only the Eskimo cook of the party. The expedition, which was under the leadership of Mr. Alan Crawford, was financed by Dr. V. Stefansson, and set out in 1921. The relief party under Mr. Harold Noice found the body of one member of the expedition, who had apparently died of scurvy, and learned that Mr. Crawford with two companions started over the ice for Siberia in December. Nothing has been heard of them since. A bottle was found in Roger Harbour on the south of Wrangel Island containing the names of the party and claiming the island in the name of King George. The relief party left one man with thirteen Eskimos behind to colonise the island and to search for the bodies of the missing men.

IN connexion with the recent correspondence in NATURE on the forms of scientific terms derived from the Greek language, Mr. A. Stanley Pye-Smith sends us a copy of an interesting letter written to "Charles Lyell, jun., Esq., F.R.S." by Dr. J. Pye Smith, F.R.S. in April 1837, and returned by Lyell in 1851 when the biography of his correspondent was being prepared. Dr. Pye Smith protests in this letter against the use of "e" to represent "ai" in Eocene, Miocene, etc., and he points out that this letter leads to obscurity, since it might equally serve as a substitute for "oe," as is the case in the word "economy." He cites several cases in which a diphthong was dispensed with for about a century and was afterwards restored (Cæsar, Phœnicia, ægis, etc.). Curiously enough, he does not criticise the first syllable of Miocene and Pliocene, in which the use of the Greek "ei" has been courageously maintained by Prof. Boyd Dawkins. International usage probably now stands in the way of any changes in either of these well-established terms.

WE have received from Messrs. James Swift and Son, Ltd., 81 Tottenham Court Road, London, W.1, a copy of their "Petro 922" catalogue of petrological

and mineralogical accessories which includes a large variety of micrometers, goniometers, refractometers, spectroscopes and other microscope accessories necessary for routine work or for special research in petrology, mineralogy and crystallography. Among the more important items described are Dr. A. Hutchinson's universal goniometer; the recording micrometer designed by Prof. Shand for geometrical rock analyses; the stage refractometer of Dr. F. E. Wright by means of which the refractive index of a liquid may be easily ascertained, with an accuracy of one or two units in the third place of decimals, on any microscope fitted with a Bertrand lens and a micrometer scale in the ocular; and the tank refractometer designed by Mr. A. F. Hallimond and Dr. H. H. Thomas, which affords a convenient means for determining the refractive indices of liquids in bulk and is useful for expeditiously preparing standard fluids for testing the refractivity of minerals. A price list accompanying the catalogue shows a general reduction in the prices of the apparatus listed.

MR. H. LING ROTH, of the Bankfield Museum, Halifax, has in the press a work on "The Maori Mantle," with numerous illustrations and plates.

THE *Annali di Chimica* is a new journal published at Trieste, devoted to chemical and "astrochemical" matters. The second number, which we have just received, contains articles on the atom, on Sirius and other stars, and on the transmutation of base metals into gold (reprinted from another journal).

ALL who were attracted by the sumptuous art books of Mr. A. Thorburn on "British Birds" and "British Mammals" will be interested to learn that the same author and artist is bringing out through Messrs. Longmans and Co. in the autumn a further work entitled "Game Birds and Wild-fowl of Great Britain and Ireland," with 30 plates in colour showing 58 species. The volume will be issued in two forms, one being on large paper, limited in number to 155 copies.

AMONG the forthcoming books announced by the Cambridge University Press are the following: "Life," by Sir A. E. Shipley, which will form an introduction to biology for the general student; "Physical and Chemical Science," by W. C. D. Whetham; "The Structure of the Atom," by Dr. N. R. Campbell, being supplementary chapter No. 17 to "Modern Electrical Theory"; and a new and revised edition of Prof. G. H. Hardy's "Orders of Infinity: the *Infinitärcalcul* of Paul Du Bois-Reymond," in the Cambridge Tracts in Mathematics and Mathematical Physics.

Our Astronomical Column.

CALENDAR REFORM.—The League of Nations, in addition to the grave political problems which confront it, has found time to appoint a committee to deal with the question of Calendar Reform, more especially as relating to the determination of the date of Easter. The principal religious bodies are represented, the Church of England by Rev. T. E. R. Phillips, secretary of the Royal Astronomical Society. In this connexion an interesting letter, signed "Astronomicus," appeared in the *Times* for August 27. It quoted a resolution adopted by a council representing the Greek and allied churches that was held last May in Constantinople. This extended to ecclesiastical purposes the use of the Gregorian calendar, which had been adopted for civil purposes in Greece some months previously. Thus the Gregorian calendar has now finally superseded the Julian one in Europe, though the process has occupied 340 years.

The resolution also affirmed the willingness of the churches concerned to modify the method of determining Easter, provided it was kept on a Sunday subsequent to the first full moon after the equinox. This condition would be satisfied if Easter were the first Sunday after April 20; this is a later date than most of those suggested, which have been near the middle of the present range, extending from March 22 to April 25.

STELLAR POSITIONS AND THE EINSTEIN LIGHT-BENDING.—The idea has occurred to many people that the Einstein light-bending by gravitation, the existence of which was confirmed at the eclipses of 1919 and 1922, might produce appreciable displacements in the apparent position of stars if their rays passed close to other stars on their way to our system. Signor O. Z. Bianco, of Turin, in a note to us, quotes Bessel's view that the number of dark stars may greatly exceed that of the lucid ones, and infers that serious displacements of the positions of the latter may result. A little consideration will, however, make it plain that the number of cases where the necessary conditions prevail must be extremely small, and even in these cases the proper motions of the three bodies concerned (lucid star, dark star, sun) would quickly modify them, so that the large shift would be of very brief duration.

A ray passing at a distance of one astronomical unit from the sun is deflected through an angle of 0·01″. A study of the stellar masses shows that only a very small minority of the stars have masses greatly in excess of the sun's. Moreover, the majority of the stars are at such distances that an astronomical unit subtends an angle of less than 0·01″. Even if we supposed the dark stars to outnumber the lucid ones a thousand-fold, there would be very few cases of two independent stars approaching each other so closely in direction; but, as a matter of fact, dynamical researches on the stellar motions give no support to the existence of such a large preponderance of dark stars.

It may further be pointed out that shifts of the order of 0·01″ in the positions of stars are quite unimportant, being far below the probable errors of the best catalogues. As an illustration of this it may be mentioned that the correction of meridian observations for the Einstein shift due to the sun has not been suggested by any one, though it would frequently mount to 0·02″. It has already been mentioned in these notes that the Einstein displacement has no effect on the relative positions of binary stars, but only comes into play when one orb is far behind the other. The argument outlined above shows that Signor Bianco's fears are groundless, and that no appreciable errors in star-positions from the cause mentioned are to be apprehended.

Research Items.

EXCAVATIONS AT CIRENCESTER.—Some recent important discoveries at Cirencester are described by Mr. St. Clair Baddeley in vol. xliv., 1922, of the Transactions of the Bristol and Gloucestershire Archæological Society. The remarkable fact results from the excavation of the city wall that portions of it, at any rate, are not of Roman Imperial construction or formed, as has been hitherto accepted, during the late Empire, so as to enclose the then far-expanded, but not yet endangered, Corineum; but that they are of precisely identical character with the dry-walled mounds that encircle many other Cotteswold settlements, made by pre-Roman tribes. In the former case the probability seems to point to the Dobuni, or a previous people, the Cornavii, as the makers of the wall; these mound-enclosures have been in later times occupied in the extension of Roman Cornubium. Mr. Baddeley's paper is illustrated by photographs of the excavations.

TABLET-WEAVING IN ANCIENT EGYPT.—Mrs. Crowfoot and Mr. H. Ling Roth have reprinted a paper from the Annals of Archæology and Anthropology (vol. x., Nos. 1-2), entitled "Were the Ancient Egyptians conversant with Tablet-weaving (Brettchenweberei, Tissage aux Cartons)?" They dispute the theory that tablet-weaving is the origin of all weaving, as has been asserted by Herr H. Pralle. No authentic tablet-weaving tools have yet been found, and the art is not known to be depicted on any wall or other illustration in Egypt. After a careful review of weaving technique, illustrated by numerous drawings, the writers arrive at the conclusion that no tablets have been found earlier than Coptic days, and those of doubtful provenance, and all ancient Egyptian textiles examined by them were certainly not tablet-woven; there is at present no evidence whatever for tablet-weaving in ancient Egypt.

WOOD CARVINGS FROM THE CONGO AND WEST AFRICA.—Mr. H. V. Hall continues in the June issue of the Philadelphia *Museum Journal* his account of a collection of wood carvings from the Congo and West Africa. The article is fully illustrated and describes some remarkable specimens of West African work. The question of foreign influence on this type of native art is not clear, but most of the specimens seem clearly to be indigenous work. The Kroos, at any rate, have been for a long period closely associated with Europeans, and one image seems to represent a Captain Hunt, the master of a steamer, who is seated on a barrel which may have contained nails, or its contents may have been of a liquid nature. The characteristic carelessness of the Negro craftsman in matters of detail is shown by the fact that though the opening of the tight jacket is carefully indicated by a line down the front, yet this is shown folding right over the left, there are no buttons, and no division is marked between jacket and trousers.

APPRECIATION OF TIME.—"An Experimental Study of the Appreciation of Time by Somnambules" is the title of an article by Mr. Sidney E Hooper in the Proceedings of the Society for Psychical Research for July. It is known that some hypnotic subjects display what appears to be a supernormal power of appreciating the passage of time. If, for example, such a subject is told during hypnosis to perform some simple act at the end of 5000 minutes he will do so, at or about the correct time, although in the period intervening between the hypnosis and the performance of the act he has had no conscious knowledge of the suggestion that has been given to him. Experiments demonstrating this peculiarity of the hypnotic state have been recorded by Gurney, Delbœuf, Milne Bramwell, and Mitchell, and Mr. Hooper takes up the inquiry at the point at which it was left by these observers. Two main problems are presented by the results of these experiments: (1) the subliminal calculation by which the subject comes to know the time at which the suggested act is to be performed; (2) "true time-appreciation," by which the subject knows when the time so calculated arrives. When a long time-interval is given in minutes the subject usually calculates subliminally so as to find out when the suggested act falls due. Mr. Hooper's experiments corroborate this; but one of his subjects maintained that as soon as the suggestion was given she began to count rhythmically and continued to do so until the suggested number of minutes had elapsed. It is to such a capacity for accurate counting of seconds by a subconsciousness on which the pendular rhythm of the clock has been faithfully inscribed that Mr. Hooper looks for an explanation of "true time-appreciation."

CALIFORNIAN POLYCHÆTES.—Dr. J. Percy Moore (Proc. Acad. Nat. Sci. Philadelphia, vol. 75, 1923) completes the account of the polychætes dredged off the coast of South California. His three previous papers, published respectively in 1909, 1910, and 1911, dealt with the Nereidiformia, and the present report contains the systematic account of the other suborders. Thirty-three new species are described.

ALPINE WATER-MITES.—Dr. C. Walter's memoir on the Hydracarinæ of alpine waters (Denkschr. Schweiz. Naturforsch. Ges., Bd. 58, 1922), together with previous accounts of Italian investigators of the more southern forms, provides a fairly complete account, at least of the faunistic aspect, of these fresh-water mites. The author has been collecting since 1906, and specimens have been obtained from 433 localities in the basins of the Rhone, Rhine, Danube, and Po. The systematic descriptions are followed by a short comparative account of the eggs and of the larval and nymphal stages. Attention is directed to the great importance of the larval stage in regard to the distribution of many of the species; the larva fixes itself to some insect, inserts its mouth-parts through the skin of its host and so feeds, being meantime transported by the host. The author gives interesting notes on the adaptations met with, *e.g.* the rich development of hairs on the legs of swimming species, the dorso-ventral flattening of the body—and with this a hardening of the dorsal chitin—usual in fluviatile species. The Hydracarinæ of alpine waters may be divided into two groups—the eurythermic species, mostly living in still water, highly adaptive and resistant, and widely distributed; and the stenothermic species, not tolerant of extensive changes of temperature but finding their optimum in water of low temperature, more limited in their range, and found chiefly in the springs and on the shores of high alpine lakes. The author discusses the origin of these two groups—the first largely composed of species which in post-glacial times spread westwards from Central Asia, and the second for the most part a remnant of the glacial fauna. He puts forward anatomical and other evidence indicating the origin of these fresh-water mites from marine mites (Halacaridæ).

NEMATODES OF SHEEP AND CHICKENS.—The two principal communications in the current issue of the *Journal of Helminthology* (vol. i. pt. 3, 1923) are a careful account by T. W. M. Cameron of the anatomy

of *Monodontus trigonocephalus* of sheep, and a description by Dr. R. J. Ortlepp of the life-history of *Syngamus trachealis*, the gape-worm of chickens. The eggs in the uterus of the female Syngamus do not develop there beyond the 16-cell stage, and they are usually laid in this or in the 8-cell stage, and when kept in well aerated water at 25° C. they take about a week to develop into infective larvæ, undergoing one moult during this period. The second stage or infective larvæ are sheathed; they are non-climbers, do not penetrate the skin, and cannot resist desiccation. Larvæ swallowed by chicks reach the lungs in about 24 hours. The path of migration from the digestive tract has not been traced but the author inclines to the view that the larvæ are carried like those of Ascaris and Ancylostoma, *i.e.* in the blood-stream through the heart to the lungs. In the lungs the larvæ grow considerably and undergo two further moults, the final or fourth stage being reached in about five days after infection. The young worms then pair and migrate into the trachea, where, 10 to 14 days later, they attain sexual maturity. Thus the whole life-cycle is completed within a month. Dr. Ortlepp supports the view of Walker and Waite that, in Nature, chickens contract the infection by eating earthworms infected with the larvæ.

A PHYSIOLOGICAL FUNCTION OF THE PITUITARY GLAND.—The chemical constitution of the active substances extracted from the posterior lobe of the pituitary gland is still unknown, but their important pharmacological properties have received much attention and are accurately determined. Until recently, however, the physiological functions of the organ remained a matter for speculation. In a series of researches on pigmentary changes, L. T. Hogben and F. R. Winton have now succeeded in defining such an essential endocrine function in amphibia. They showed (Proc. Roy. Soc., 1922, B, vol. 93, 318-329) that injection of traces of posterior lobe extracts into pale frogs (melanophores contracted) induces profound darkening of the skin (expansion of the melanophores). This action is not elicited by other tissue extracts, whereas the minute posterior lobe of a single frog includes enough active substance to darken at least fifty other pale individuals. So sensitive is the reaction that it may serve as a method of detection or of rough estimation of the potency of such extracts (*Biochem. Journ.*, 1922, vol. 16, 619-630). This response is a direct action on the skin, as can be demonstrated by experiments on the isolated skin, and by the inefficacy of drugs with paralytic action to prevent it. Stimulation of nerve trunks and the administration of the drugs showed no direct evidence of nervous mechanism for pigment control (Proc. Roy. Soc., 1922, B, vol. 94, 151-162). After extirpation of the whole of the pituitary gland the skin always became quite pale and the melanophores completely contracted. This pallor persisted permanently even in the presence of the optimum conditions (cold, wet, and shade) for darkening of normal animals. Injection of posterior lobe extracts was followed by profound darkening with complete melanophore expansion, which lasted for a varying time according to dosage and other conditions, the animals then returning to permanent pallor. Frogs from which anterior lobes only were removed, or with the brains exposed, were indistinguishable from normal animals with respect to their pigmentary reactions. The failure of colour response associated with complete hypophysectomy is therefore due to absence of posterior lobe secretion, and not attributable to anterior lobe deficiency or to the operative technique employed (Proc. Roy. Soc., 1923, B, vol. 95, 15-30).

THE ETHYL ALCOHOL INDUSTRY.—The *Chemical Trade Journal* for August 3 prints a review of the ethyl alcohol industry. The pioneer of synthetic alcohol was Hennell, who, in 1828, found that dilution and distillation of a sulphuric acid solution of ethylene yielded alcohol; this reaction also has considerable theoretical significance. During the War, much alcohol was made from acetylene, which in its turn was produced from synthetic calcium carbide. The acetylene was hydrated directly to acetaldehyde (in the presence of a mercury salt), which was then reduced to alcohol by the Sabatier and Senderens' reaction. Under present economic conditions Germany appears to make most of her alcohol by fermentation methods. The article includes a survey of the physical properties of alcohol, its industrial applications and future prospects for the synthetic product.

CELTIUM OR HAFNIUM?—*Chemistry and Industry* for August 10 contains an important article by Prof. G. Urbain under the title "Should the Element of the Atomic Number 72 be called Celtium or Hafnium?" Prof. Urbain claims that he has had this element in his possession and under his observation since 1911, when he suggested the name celtium for it; that although Moseley in July 1914 (when Urbain visited him in Oxford) was not able to detect the characteristic lines of No. 72 in the fraction submitted for test, two of these lines were, in fact, detected by Dauvillier in 1922, in the spectrum of the same material, by making use of improved experimental methods; that if any doubt existed as to the identity of these lines, it was finally removed by a direct comparison (by the method of coincidences) of lines from the 1911 fraction with a newly-prepared fraction from a zirconium mineral, in which the presence of No. 72 is not now questioned, in view of the *six* characteristic lines recorded by Coster and Hevesy. Under these conditions the claim of the later workers to have discovered a new element (since it could scarcely be based on a more accurate measurement of the same physical property) appears to depend on the assumption that a "fourth group" element *could not have been present* in the rare earth fractions examined twelve years previously by Urbain. Prof. Urbain claims that it was actually there, and that there is no theoretical objection to its presence, since "there is no law which compels the elements to associate themselves strictly in accordance with their classification." Moreover, he had already, in 1921, himself agreed to Perrin's classification of celtium as a fourth-group element, in spite of the fact that he had found it in a rare-earth mixture. He points out that there are many elements with different valencies which cling together so closely that one cannot separate them except by very laborious treatment, and in particular that thorium, which is quadrivalent, is in fact always accompanied by the tervalent rare earths. Again, Bohr's theory only applies to free atoms and simple ions, and affords at present no guidance whatever as to the behaviour of complex ions; it is therefore not able to predict the chemical properties of elements which form double-salts in solution. These give rise, however, to many surprising cases of complete isomorphism, *e.g.* the fluorides of quadrivalent titanium with the oxyfluorides of quinquevalent niobium. Prof. Urbain claims that "no purely theoretical reasoning ought to prevail against a well-established question of fact," and that as regards the presence of celtium in his rare-earth fractions, the facts are not only well established but also in strict accord with general chemical experience.

The Gaseous Nebulæ.[1]

By J. H. Reynolds.

It has been recognised for many years that the nebulæ fall into two great divisions—the spirals and the gaseous and diffuse. The distinction between the two is fundamental, for there can be no doubt now that the spirals are extra-galactic, and the gaseous inter-galactic formations, although it is impossible yet to define the scale and distances of the spirals with any certainty. Since Huggins's great discovery of the gaseous nature of certain nebulæ, the principal work on these objects has been done in America, especially at the Lick Observatory and at Mt. Wilson; and coupling up these investigations with recent advances in physics in which Great Britain has played no mean part, we are able to form a good general idea of the meaning and origin of the gaseous nebulæ.

The first important fact which emerges from the physical work of Fowler, Saha and others, is that only the elements of simplest constitution, such as hydrogen and helium, are known to be present, and that ionisation of known elements is probably responsible for all the unknown lines in the nebular spectrum. Then, again, the gaseous nebulæ are only associated with stars of the highest temperature, as the stars in the centre of the planetaries are usually "O" type stars of the Harvard scale, which yield an emission or absorption spectrum of ionised helium on a continuous background, and the "B" type stars, which are next in order of temperature, and are associated with the irregular gaseous nebulæ in Orion. Until recently it was supposed that the so-called "nebulium" identified with the nebular radiations at λλ5007 and 4959, and other well-known lines such as λλ4363, 4686 and 3727, represented unknown gases in the same sense that helium was unknown until identified in the laboratory by Sir William Ramsay, but the work of Moseley and Aston and the formation of the scale of atomic numbers has taught us that there is no room for any more unknown elements in the atomic scale of the lighter gases, and we must look in the direction of ionisation of the known elements in the first ten numbers of the scale for these unknown nebular lines.

These considerations and the progressive spectra of Novæ lead to the conclusion that in all gaseous nebulæ we are dealing with the same material, and that the differences found in the spectra are to be assigned to differences only in physical conditions, and the key to these conditions is to be found in the effective radiation of the star or stars involved in the nebula. Only the first two numbers of the atomic scale are definitely established as appearing in nebular spectra, the helium appearing often near the nuclear star in its ionised form. But Wright in Lick Observatory Pub., vol. xiii., provisionally identified certain nebular lines with carbon and nitrogen, and the presence of the former at any rate is now accepted.

The principal nebular lines of unknown origin are the following:

$$\left.\begin{matrix}\lambda 5007\\ \lambda 4959\end{matrix}\right\}\lambda\lambda 4363,\ 4340,\ 3868,\ 3727\text{–}9.$$

The first two are invariably found in all the gaseous nebulæ in the same relative strength, and they evidently form a doublet. λ5007 was the first gaseous radiation to be discovered in a nebula, and with its companion it exists in a very marked form in nearly all the objects of this class yet observed. The other radiations vary much in relative strength, and sometimes seem to be absent altogether. Perhaps the most remarkable is that usually described as λ3727, which has been found by Wright to be in reality a doublet separated by only two Ångström units. It is astonishingly brilliant in the Orion Nebula, and with the hydrogen radiations it is responsible for the great photographic effect of this object. It is always of maximum extension, and is found in regions far removed from the involved stars, where the hydrogen radiations are comparatively faint. An investigation by means of screened direct photographs was undertaken by the writer some years ago as to the relative distribution of the doublet λ(5007, 4959), the hydrogen series, and λ3727 in the Orion Nebula. The principal results were:

(1) To establish Keeler's conclusion that the doublet λ(5007, 4959) was conspicuous only in the central region surrounding θ Orionis, where it was very brilliant.

(2) To demonstrate that the hydrogen radiations extended faintly to the most remote regions of the nebula, and

(3) To show that the radiation λ3727 was much stronger than the hydrogen in these outer regions, besides giving certain differences in detail.

We have then in the Orion Nebula a bright central portion where the radiations λ(5007, 4959), the hydrogen and helium radiations and λ3727 are integrated together, an intermediate region where hydrogen and λ3727 appear of about the same strength, and an outer region where λ3727 predominates. There is no difficulty in ascribing λ(5007, 4959) probably to an ionised form of one of the elements heavier than helium, as we should expect the heavier elements to predominate in the central regions surrounding the star θ and the other involved stars. There is, however, very great difficulty in explaining the distribution of λ3727. It must be remembered that the "B" type stars involved in the nebula are not of the highest stellar temperature, and it is almost impossible to imagine the existence of ionisation at all in these remote regions. There is, indeed, good reason for thinking that λ3727 is a comparatively low temperature radiation, as it is either faint or absent altogether in the planetaries containing "O" type stars, and it does not occur so far as can be ascertained in the nebular stages of Novæ.

An interesting point bearing on the distribution of this radiation is brought out by an examination of the nebulosity surrounding the star Bond 734 to the north of the principal nebula. In the screened exposure of the radiations λ(5007, 4959) no nebulosity appears round this star, and the absence of these radiations is confirmed in Lick Observatory Pub., vol. xiii. The hydrogen image is quite strong, and is accompanied by an equally strong image in λ3727. It is quite evident, therefore, that there is no direct relation between the radiations λ(5007, 4959) and λ3727, and it is known that the hydrogen radiations occur without either. But the question arises as to whether λ3727 can exist independently of hydrogen. The differences of detail visible in the photographic images given by hydrogen and λ3727 certainly suggest an independent origin, but a complete answer to the question is impossible, as hydrogen is found in varying strength in all the gaseous nebulæ and novæ. If it were not an impossibility, one would naturally look for the radiation as some element actually lighter

[1] Substance of an address delivered before the Birmingham University Physical Society on March 14, 1923.

than hydrogen. The origin of this radiation λ3727, therefore, seems to be one of the most interesting and difficult problems which the astrophysicist has to deal with at the present time.

We will now pass on from the Orion Nebula, which may be taken as a good example of the irregular gaseous nebulæ connected with "B" type stars, to the planetaries. Here we have to deal with involved central stars which are of the "O" type, of a considerably higher temperature. In the spectra of these nebulæ the doublet λ(5007, 4959) is still usually the strongest radiation, and hydrogen is invariably present. On the other hand, λ3727 is often comparatively faint or absent altogether, although λ3869 is still one of the strongest radiations in the spectrum. Ionised helium at λ4686 is also very conspicuous, but does not extend far from the nucleus, showing that ionisation only takes place in the neighbourhood of the star itself. Another bright radiation at λ3426, found in the spectrum of Nova Cygni III, also makes its appearance, but its extension from the nucleus is small.

A very remarkable feature in the high dispersion spectra obtained with the three-prism spectrograph of the Lick 36-in. refractor was the character of the lines under magnification. When the slit of the spectrograph was placed across the major diameter of the planetary nebula disc, the resulting lines in the doublet λ(5007, 4959) were not parallel-sided, but spread out in the centre, each end being slightly curved in opposite directions. If we are to interpret this phenomenon on the Döppler principle in the usual way, this means that the gases are both receding from us and advancing towards us in the line of sight, coupled with a slight rotation of the gaseous spheroid as a whole. The only feasible explanation is that the gaseous shells forming the nebula are still expanding, and we are at once led to a comparison with novæ such as Nova Aquilæ III, which now has developed an expanding gaseous disc.

The later spectroscopic stages of novæ are comparable in every detail with the planetary nebulæ; the galactic distribution of both is similar, and the evidence is now overwhelming that the planetaries had their origin in novæ, and the gaseous shells of the planetaries are the remains of past outbursts. It may be asked why the planetary nebulæ are comparatively few in number, but it is evident that if the central star fell to a lower temperature than the "B" type, the radiation would be insufficient either to keep the gases in a state of equilibrium or to illuminate them, and the aspect of a planetary nebula would disappear. The same remarks apply to objects like the Orion Nebula connected with "B" type stars. Here the radiation energy is not so intense as the "O" stars, and we do not get an equal degree of ionisation: the strength of the radiation λ3727 is also evidence of different physical conditions, but the Orion and other irregular gaseous nebulæ have every appearance of being swept away from the involved stars, and they all probably indicate a former outburst of several stars culminating in an "O" type of spectrum and a high radiation pressure.

The old idea that the gaseous nebulæ were the primitive forms of matter from which stars were evolved must, it seems, be given up for the exactly contrary hypothesis that they had their origin in stellar outbursts, where matter passed from complex to simpler forms by atomic disintegration under the stress of extreme temperature development.

Plants in Relation to the Health of Man.[1]

CINCHONA, the plant which yields quinine, known under the name of "Jesuits' Powder" since 1655, was introduced into India about the years 1858 to 1862. Seedlings and seeds were brought to Great Britain from the Andes of Bolivia during those years, principally by Sir Clements Markham and Mr. Richard Spruce, and the plants, which were raised at the Royal Botanic Gardens, Kew, were taken to India and Ceylon. The cultivation in India was mainly established in the Nilgiri Hills and in Sikkim. The three species of Cinchona which are particularly valuable as sources of quinine are *C. Calisaya*, *C. Ledgeriana*, and *C. succirubra*.

The Dutch had also been experimenting with Cinchona and established the plant in Java about the same time as the English were introducing it to India. So successful have the plantations been in India, thanks to the labours of Dr. Thomas Anderson, Sir George King, Messrs. Wood and Gammie and Sir David Prain, that in every post office in India it is now possible to procure doses of from seven to ten grains of pure quinine for a *pice*, which is about equal to a farthing. In this way, more than eight thousand pounds avoirdupois of quinine are distributed yearly, and in addition to this a large supply is furnished to hospitals, etc. Efforts are now being made to extend the cultivation of quinine in Malaya and Burma. Substitutes for Cinchona as a source of quinine were used in the Cameroons by the Germans during the War.

Other interesting plants are Efwatakala grass, *Melinis minutiflora*, which is reported to be obnoxious to the tsetse fly; citronella grass, the source of lemon grass oil, which is repellent to mosquitoes; and *Ocimum viride*, the Basil plant, which at one time was thought to be repellent to mosquitoes, but now is known to be of no value for the purpose.

In connexion with the preservation of the health of man in temperate climates, the plants yielding india-rubber are of first importance. The principal source of india-rubber is *Hevea brasiliensis* (Para rubber). This again is a native of South America. Seeds and young plants have been distributed to the various tropical colonies of the British Empire since the year 1873, when it was brought over from South America, mainly owing to the successful efforts of Sir Henry Wickham. Other sources of rubber are the Ceara rubber, *Ficus elastica*, Funtumia, and the tropical African Landolphias. The rubber now used commercially is mainly derived from plantations in the East, to which region it was introduced through the Royal Botanic Gardens, Kew.

Another source of protection against damp and cold is furnished by the various plants which yield tannin, the preservative of leather. The principal sources of this are oak galls and bark, mangrove bark, Myrobalans, Quebracho, and *Acacia decurrens*. Extensive plantations of the latter plant, which is a native of Australia, have been made in South Africa and are a source of considerable wealth to Natal.

Cinnamomum Camphora, which is a native of Formosa, is the source of camphor, valuable as a drug and also a preservative of clothing against moth. Trade in camphor is a monopoly of the Japanese, but seeds have been freely introduced to British colonies, largely through the agency of Kew. It is now found there are two forms of camphor, but only one of these yields the solid camphor which is of value.

Erythroxylon Coca is the source of cocaine, the alkaloid which has so many useful as well as harmful effects.

[1] From a Chadwick public lecture delivered by Dr. A. W. Hill, F.R.S., at the Chelsea Physic Garden, on June 13.

The Liverpool Meeting of the British Association.

THE following Dominion and foreign representatives are expected to be present at the Liverpool meeting of the British Association which begins on Wednesday next, September 12. In the programmes of the various Sections, published in last week's issue, announcement was made of papers to be read by these visitors and of discussions in which they will take part.

Prof. F. D. Adams, McGill University, Montreal.
Prof. W. D. Bancroft, Cornell University, Ithaca.
Prof. N. Bohr, Institut for Teoretisk Fysik, Copenhagen.
Mr. S. C. Brooks, Hygienic Laboratory, Washington.
Dr. Herbert Bruce, University of Toronto.
Prof. A. H. R. Buller, University of Manitoba, Winnipeg.
Senatore Principe G. Conti, Florence.
Dr. D. Coster, Copenhagen.
Prof. P. Ehrenfest, University of Leyden.
Prof. E. Ekwall, University of Lund.
Prof. A. S. Eve, McGill University, Montreal.
Dr. K. G. Falk, New York.
Prof. J. C. Fields, University of Toronto.
Prof. V. M. Goldschmidt, Universitetets Mineralogisk Institut, Kristiania.
Prof. V. E. Henderson, University of Toronto.
Dr. G. Hevesy, Copenhagen.
Prof. D. R. Hoagland, University of California.
Prof. O. Jespersen, Copenhagen.
Prof. A. E. Kennelly, Massachusetts Institute of Technology, Cambridge, Mass.
Dr. P. L. Kramp, Zoological Museum, Copenhagen.
Dr. A. C. Kruyt, University of Utrecht.
Prof. P. Langevin, Collège de France, Paris.
Dr. V. Lebfelter, Folksgesundheitamt, Vienna.
Prof. F. S. Lee, Columbia University, New York.
Prof. G. N. Lewis, University of California.
Prof. A. B. Macallum, McGill University, Montreal.
Prof. J. C. McLennan, University of Toronto.
Prof. J. J. R. Macleod, University of Toronto.
Prof. R. Magnus, University of Utrecht.
Prof. A. P. Mathews, University of Cincinnati.
Prof. E. Merritt, Cornell University, Ithaca, New York.
Prof. A. R. Moore, Rutgers College, New Brunswick, N.J.
Dr. Th. Mortensen, Universitetets Zoologiska Museum, Copenhagen.
Prof. W. A. Noyes, University of Illinois.
Prof. Sven Oden, Kgl. Tekniska Hogskolan, Stockholm.
Prof. W. A. Parkes, University of Toronto.
Prof. M. I. Pupin, Columbia University, New York.
Prof. H. M. Quanjer, Institut voor Phytopathologie, Wageningen, Holland.
Prof. Roule, Musée d'Histoire Naturelle, Paris.
Prof. R. L. Sackett, State College, Pennsylvania.
Prof. J. Satterly, University of Toronto.
Dr. Johs. Schmidt, Carlsberg Laboratorium, Copenhagen.
Prof. J. Sebelien, Aas, Norway.
Prof. H. B. Speakman, University of Toronto.
Dr. V. Stefansson, Canada.
Prof. J. Tate, McGill University, Montreal.
Prof. W. Vernadsky, Paris.
Senatore Prof. V. Volterra, University of Rome.
Dr. G. S. Whitby, McGill University, Montreal.
Prof. A. Willey, McGill University, Montreal.
Prof. R. W. Wood, Johns Hopkins University, Baltimore.
Prof. H. Zwaardemaker, Universitas Rheno-Traiectina, Utrecht.

Relativity and Theory of Knowledge.

THE *Scandinavian Scientific Review*[1]—a new quarterly in English published in Norway—contains in its first number an original and important piece of philosophical research in an article entitled "The Theory of Relativity and its Bearing upon Epistemology," by Prof. Harald K. Schjelderup, the recently appointed professor of philosophy in the University of Christiania. The author is already distinguished in his own country, although he is probably the youngest occupant of a chair of philosophy, having been born in 1895.

The article begins with a lucid exposition of the principle of relativity which calls for no special remark, but it proceeds to examine the consequence of its acceptance in physics for theory of knowledge. It is obvious that it must make a clean sweep of all naïvely realistic theories, materialistic or spiritualistic, which assume the physical reality of the universe to be presented objectively to the mind of the observer for his discernment by means of sense discrimination. But does it accord with idealism? Does it deny that there is any objective universe to which knowledge can attain? Does it require us to be content with the subjective space-time universes of individual observers? Prof. Schjelderup answers emphatically, No. Relativity gives us not a relative but an absolute universe, a universe the scientific reality of which, however, is completely different in its nature from anything which men of science have hitherto imagined or thought it necessary to assume. The Minkowski four-dimensional space-time universe is absolute, in precisely the same sense in which Newton's three-dimensional space and independent variable time were absolute, and the world-lines of the Minkowski universe with their intersecting points determined by Gaussian co-ordinates are real in the objective sense, but the reality is not sense-presented, it is unimaginable and imperceptible. It consists, like the reality of Pythagoras, of numbers.

The point of special interest in the argument is the way in which the author brings out the deciding influence in physical theory which the epistemological weakness of the older mechanics has had. It was Galileo, the founder of modern physics, who, in his discrimination between what he called the accidental and the essential attributes of things, first suggested the distinction between secondary and primary qualities, which has played a determining part in later theories of knowledge. Galileo found his interpreter in Descartes, who reduced physical reality to extension and movement. The principle of relativity has eliminated even the primary qualities from the subject-matter of physics.

Similarly in the relation of Kant to Newton, we see the directive force of the epistemological weakness of a physical theory. The subjectivity of time and space in the Kantian theory meant their transcendental ideality. Abstracted from the subjective conditions of sensory observation they are invalid. But relativity goes further, it eliminates time and space not only from an unknowable thing-in-itself, but even from the subject-matter of physics. To us to-day the principle of relativity is not a return to older philosophical concepts, but a forward movement looking for a new philosopher to interpret a new epistemology.

Pan-Pacific Science Congress, Australia, 1923.

WHILE not on so extensive a scale as, nor with the Imperial significance of, the Australian meeting in 1914 of the British Association for the Advancement of Science, the second triennial Pan-Pacific Science Congress, which has just met in Melbourne and afterwards in Sydney, may mean very much to the development of organised knowledge of, and in, countries bordering upon the Pacific Ocean. The first gathering of the kind was held in Honolulu in 1920, and as a matter of fact it was really the sequel to ideas that originated during the British Association visit to Australia and later were warmly fostered by Prof. W. M. Davis (Harvard), Prof. H. E. Gregory (Yale), Dr. T. Wayland Vaughan (U.S. Geological Survey), Mr. A. H. Ford, and others. The Pan-Pacific Union, a wide organisation with the general aim of promoting harmonious relations between the peoples of the Pacific, stood behind the Honolulu Congress, but future Science Congresses will undoubtedly all be under the general direction and control of the National Research Councils of the countries concerned.

The Commonwealth Government is acting as host for the 1923 gathering, the organisation being in the hands of the Australian National Research Council, of which Sir David Orme Masson is president. State Governments are generously supplementing the Commonwealth's financial and other assistance, and it has been possible in many cases to make grants helping to defray travelling costs for delegates from distant countries. The prevailing high rates for steamship travelling are a grave difficulty in the way of international assemblies in a region of such vast distances as the Pacific. Happily the interest of the Governments of the chief countries concerned has been aroused, and invitations, conveyed through the Colonial Office, to send official delegates, have met with much response. Unfortunately the South American Republics, with few exceptions, have regretted that their financial conditions do not permit the sending of official representatives. Even more unfortunate is it that France has not seen fit to send a delegation. Nevertheless, with eleven visitors from Great Britain, nineteen from the United States of America, three from Canada, eight from Hawaii, twelve from Japan and Formosa, nine from the Philippines, six from the Netherlands and the Dutch East Indies, eleven from New Zealand, and smaller delegations from British Malaya, Burma, Tahiti, Papua, Fiji, and Hong Kong, a very fairly representative gathering is assured. While in Australia, all visitors from overseas are the guests of private citizens or institutions and are receiving the privilege of free railway travelling before, during, and after the Congress.

To transfer a congress after ten days in one city to another some six hundred miles distant must militate against consecutive work and lead to a certain amount of overlapping; but the advantages in enabling visitors to see more of the country, and in increasing the numbers of local workers who come into personal contact with them, more than counterbalance the obvious disadvantages.

Needless to say, an extensive series of excursions has been arranged, the principal excursions, over long distances, necessarily coming after the official business in Sydney has been concluded. Visits to Broken Hill, Irrigation Areas, Artesian Water Areas, Great Barrier Reef, Northern Rivers to Brisbane, Canberra and other parts of the Commonwealth, are proposed.

The scientific work is being carried on in eleven Sections. As, however, it has been a deliberate object of the organisers to avoid a multiplicity of papers on single and more or less isolated topics, and to aim instead at broad general discussions, there are several joint meetings between Sections. The Sections comprise: I. Agriculture; II. Anthropology and Ethnology; III. Botany; IV. Entomology; V. Forestry; VI. Geodesy, Geophysics, Radiotelegraphy, etc.; VII. Geography and Oceanography; VIII. Geology; IX. Hygiene; X. Veterinary Science; and XI. Zoology.

The agriculturists are concerned chiefly with the problems presented by diseases in wheat and other cereals, sugar-cane, cotton, tobacco, bananas, etc., and on the serious difficulties to be faced in controlling weed pests. Proposals for plant quarantine regulations may represent an immediate practical outcome. Agricultural education and research, soil surveys, and irrigation questions are also being discussed, while much interest is being taken in a joint discussion with the zoologists and veterinarians upon genetics, with special reference to the improvement of farm animals.

In anthropology and ethnology the Congress is attacking the fundamental problem of how best to organise and carry out research work in the Pacific Islands before it is too late. The matter is very urgent indeed. Expressions of opinion have been invited from leading ethnologists in Great Britain who cannot be present in person, and it is hoped that, so far at least as the British islands are concerned, a practical working scheme may be evolved, to be submitted later, with the full weight of the Congress behind it, to the Commonwealth Government. Sir Baldwin Spencer, who has just returned from yet another visit to the interior, is bringing forward the allied, yet distinct, question of future research in regard to the Australian aborigines. Another wide topic under consideration, in common with the Hygiene Section, is the recent rapid decline in native population in the islands, while there are also discussions upon the physical anthropology of various Pacific types, and the race relations between them.

Botany, entomology, and forestry have much in common in several proposed discussions upon timbers, and with zoology the matter of introduced pests and their natural enemies is being taken up, especially the increasingly serious problem of checking the spread of tropical boring insects.

The physical work of the Congress centres mainly round geodesy, terrestrial magnetism, meteorology, and seismology, while the highly practical international matters of radiotelegraphic communications and determinations of longitude by wireless, are also being discussed. Solar physics research, for which many maintain that more is being claimed on the purely practical side than it will yield, and the need for its endowment by Governments, is a subject for vigorous debate.

Those members concerned with geography and oceanography are meeting with the physicists frequently, especially when discussing questions of cartography and meteorology. Definite proposals are being made for continuing and extending, by local effort, the invaluable hydrographic work of the Royal Navy, and for international collaboration in oceanographic work.

As might be expected, the largest Section is that devoted to Geology. The structure of the Pacific Basin, Post-mesozoic volcanic action in the Pacific, ore provinces, correlation of Kainozoic formations, coral reef formations, glaciation, Carboniferous and Permian problems in the Pacific Region, are among the more general matters before the Section.

Two main subjects discussed in the Hygiene Section,

at Melbourne, are mining hygiene and a general survey of the hygiene of the Pacific Region. The basis for discussion of the latter is a summary of replies received by the director of the Commonwealth Department of Health to a widely circulated *questionnaire* relating to yellow fever, malaria and filariasis, bubonic plague, small-pox, leprosy, beri-beri, hook-worm disease, and tuberculosis. In Sydney, the principal topics are climate in relation to human efficiency, meteorological standards in relation to comfort, and insects in respect to hygiene.

The work of the Veterinary Science Section is mainly in joint meetings with allied Sections, such as Agriculture and Zoology, in dealing with parasitological and other problems. Proposals are being put forward with regard to international notification of animal diseases.

Finally, the Section of Zoology is undertaking, in addition to much conjoint work with other Sections, a general survey of the many questions now arising in connexion with Pacific fisheries and the establishment of marine biological stations.

The main aim of the Congress is to deal with wide subjects, many of them of international significance, from a practical as well as a purely scientific point of view.

A. C. D. Rivett.

University and Educational Intelligence.

We learn from the *Chemiker Zeitung* of the following appointments: Dr. W. Schumann, director of the Institute of Technical Physics at Jena University, to be professor of theoretical electrotechnics at the Munich Technical College; Dr. Julius Schmidt, of the Stuttgart Technical College, to be reader in chemistry at the Engineering College, Esslingen; and Dr. K. Fajans, to be assistant professor of physical chemistry at the University of Munich.

The trustees of the Laura Spelman Rockefeller Memorial, founded in October 1918 by John D. Rockefeller in memory of his wife, have published a report on their appropriations, amounting to nearly 13 million dollars, up to December 31, 1922, on which date the corporation's assets amounted to 78 million dollars. Grants classified under the head "Education" amounted, in the four years 1919–1922, to 6000, 9000, 286,000, and 500,222 dollars respectively, and included 30,000 in 1921 for the American College for Girls at Constantinople, 110,530 dollars in 1922 for Robert College of Constantinople, the American University of Beirut, and the Constantinople Women's College, and 600,000 dollars for the Women's Union Christian Colleges in the Orient. For boy scouts and girl scouts grants amounting to 193,000 dollars were allocated, and an appropriation which will amount to more than 55,000 dollars was made for the inauguration of courses of instruction for scout leaders in universities and women's colleges. Such courses, it is noted, are given in 42 institutions, and in 13 of them the expense of instruction has already been taken over by the college. Scientific research interests the trustees because they "believe that knowledge and understanding of the natural forces that are manifested in the behaviour of people and of things will result concretely in the improvement of conditions of life," but grants for promoting it have hitherto been small: 13,000 dollars in 1921 and 37,500 in 1922, including 10,000 for the Mme. Curie Radium Fund. The Y.M.C.A. and Y.W.C.A. and other social welfare organisations received 3,299,000 dollars; religious organisations, 1,975,000; emergency relief, 1,543,000; and public health, 692,000.

A report on the development of higher education in Poland has been issued by the Chief Statistical Office of the Polish Republic. For the five State universities the report shows the following student enrolments:

	Cracow.	Warsaw.	Lwów.	Poznań.	Wilno.	Total.
1920–21 . .	4136	5787	3639	2094	788	16444
1921–22 . .	4531	7518	4773	3273	1729	21824
1922–23 . .	5235	8939	5646	3416	2202	25438

For the technical State schools the respective numbers are:

	T.H. Sch., Warsaw.	T.H. Sch., Lwów.	Agric. Coll., Warsaw.	Sch. of Min., Cracow.	Total.
1920–21 . .	2931	2178	787	179	6075
1921–22 . .	4112	2305	761	282	7460
1922–23 . .	3868	2560	906	462	7796

The following figures show the number of students admitted in 1922–23 to other higher schools and professional colleges: Independent University, Lublin, 1120; Free Polish University, Warsaw, 1664; College of Commerce and Economics, Warsaw, 988; Veterinary College, Lwów, 327; Teachers' College, Warsaw, 124; School of Fine Arts, Cracow, 155. Of the total number of students, about 24 per cent. were women. Nearly 27 per cent. were enrolled in faculties of jurisprudence, 13 per cent. in faculties of medicine, 17 per cent. were engaged in the study of technology, mechanical and electrical engineering, etc., about 6 per cent. were students of agriculture, and 30 per cent. devoted themselves to the study of philology, history, mathematical and natural science, philosophy, and education.

Lists of colleges and universities "accredited" by various agencies are published in Bulletin, 1922, No. 30, of the United States Bureau of Education. The standardising movement has advanced rapidly during the past ten years, and the lists published in 1917 already need revision. The agencies in question are: certain State universities and departments of education, the Carnegie Foundation for the Advancement of Teaching, the Association of American Universities and several other voluntary educational associations, and church boards of education. The Bureau is careful to announce in large type that "there is no comprehensive classification of collegiate institutions by any national governmental agency." The longest of the lists is that drawn up by the University of California of 286 institutions from which holders of bachelor degrees representing the usual college course of four years will be admitted to its own graduate division. Commenting on the lists, the compiler notes that the standards used are very various and the basis of classification in some cases is very vague, while "there is no practical consensus of opinion as to what constitutes that much-talked-of entity, the standard college." He finds ground for hope of a coming approximation to uniformity in this regard in the fact that a committee appointed for the purpose by the American Council on Education has formulated certain principles and standards for 4-year colleges and universities which have been adopted in whole or in part by some of the accrediting agencies. Among these principles are: "Teaching schedules exceeding 16 hours per week per instructor, or classes (exclusive of lectures) of more than 30 students, should be interpreted as endangering educational efficiency"; and "the minimum annual operating income, exclusive of payment of interest, annuities, etc., should be \$50,000, of which not less than \$25,000 should be derived from stable sources, other than students, preferably from permanent endowments."

Societies and Academies.

PARIS.

Academy of Sciences, August 6.—M. Guillaume Bigourdan in the chair.—A. **Lacroix**: Comparison of the chemical composition of two Iceland lavas, characterising eruptions of which the kind of dynamism is different. Analyses of five lavas and basalts from Katla and Hecla. As regards the distinction between quietly flowing and explosive eruptions, the author holds that the fluidity of the magma is not the only explanation of the different types of eruption, since a fluid magma, which according to Washington, should flow out quietly, if suddenly cooled on its egress into the air, may give rise to an explosive eruption. The eruption of Hecla is an example of this: the fluid lava had to force its way through the ice cap of the Myrdalsjökull glacier and the eruption throughout was of the explosive type.—G. **Bigourdan**: Project of a new catalogue of the French learned societies.—André **Blondel**: A rational method for tests and specification of triode lamps intended to work as valves. An outline of tests to be made partly at the works where the lamp is constructed, and partly at the laboratory where the lamp is to be used.—Charles **Nicolle**, E. **Conseil** and A. **Cuénod**: Preventive vaccination against acute conjunctivitis due to the Weeks bacillus. Its importance in the campaign against trachoma. Details are given of the preparation of the vaccine and of the results of experiments demonstrating the protective action of the vaccination.—Nilos **Sakellariou**: Oblique linear curvature and total geodesic curvature.—F. H. **van den Dungen**: Some technical applications of integral equations.—Rolf **Nevanlinna**: The theorem of M. Picard.—R. **de Fleury**: Elastic stability and modern materials of construction.—A. **Grumbach**: The superposition of electromotive forces in batteries with a fluorescent liquid.—R. **Levaillant**: Fluorescence and photochemistry. A certain number of fluorescent colouring matters (uranine, methylene blue, eosin, erythrosine) dissolved in glycerol or other polyalcohol, when submitted to light in the absence of air change colour, owing to hydrogenation by the alcohol. The original colour is more or less completely restored by the action of air.—G. **Vavon** and S. **Kleiner**: Catalytic hydrogenation and steric hindrance. The study of some heptenes. The addition of hydrogen to four isomeric heptenes (ethylpropylethylene, dimethylisopropylethylene, methyldiethylethylene and trimethylethylethylene) was studied in the presence of platinum black. It was found, in agreement with the theory of steric hindrance, that the hydrogenation was more difficult the greater the number of substituting radicles.—V. **Agafonoff**: The comparative study of some methods of chemical analysis of the humus in soils. A comparison of the amounts of carbon in soil determined by combustion, by the ordinary sulphochromic process, and by Simon's method (with silver bichromate). The dry combustion and Simon's method are in good agreement: the ordinary wet combustion with sulphuric and chromic acids only gives low results.—Pierre **Lesage**: Anomalies of the fruit of *Capsella Bursa-pastoris*, caused by the presence of salt in the soil.—L. **Blaringhem**: The biological control of the influence of manures: determination of the sensible periods.—Robert **Stumper**: The chemical composition of the nests of *Apicotermes occultus*. The nests are made of sand, cemented together with about 15 per cent. of organic secretion.—J. **Benoit**: The origin of the interstitial cells in the testicle of the domestic cock.—Et. **Burnet**: Irregular reactions of the filtrate from broth culture in goats infected with *Micrococcus melitensis*. If the infection by this Micrococcus renders the goat as sensitive as man to the inoculation of a small quantity of filtered culture, this reaction should afford a rapid and certain means of recognising infected goats and preventing the use of their milk. It has been proved, however, that the reaction is very irregular, and some goats, certainly infected, do not show the reaction at all. The conclusion is drawn that the filtrate creation cannot be used in practice as a means of diagnosing *Melitensis* in the goat.

August 13.—M. Guillaume Bigourdan in the chair.—A. **Lacroix**: The signification of the alkaline granites very rich in soda. The study of the rocks collected from the island of Rockhall has shown that rockallite, described as a persodic granite, has no real geological existence. Chemical analyses of various portions of the granite and its enclosures are given.—Torsten **Carleman**: Functions indefinitely derivable.—Jules **Baillaud**: Studies on the distribution of the energy in stellar spectra made at the Pic du Midi Observatory in 1920 and 1921. The spectra of nine stars have been studied. The arrangement of apparatus and method of carrying out the observations are described: the details of the experiments and the results will be published elsewhere.—R. **de Mallemann**: The theory of rotatory polarisation.—J. **Bathellier**: Correction relating to the nests of Eutermes. In a preceding note a series of fungus beds forming part of an ant nest have been described as belonging to *Eutermes matangensis*. It would appear that this view was incorrect: the structures are probably the work of an insect determined by M. Bugnion as *Microtermes incertus*.—E. **Bugnion**: Remarks on the note of M. Bathellier.—O. **Duboscq** and H. **Harant**: Sporozoa of the Tunicates.

Science and Publicity.

IN his presidential address to the British Association on Wednesday last, on the electrical structure of matter, Sir Ernest Rutherford dealt with a subject of fundamental scientific importance, as well as of popular interest—possibly on account of the conception of flying atomic projectiles and their disintegrating effects. The Association thus opened its proceedings this year with a discourse which is likely to make a wide appeal. Whether members of the general public who have not themselves made scientific observations or experiments can have an intelligent comprehension of the true inwardness of work and theory on atomic structure, or on many of the other intricate subjects dealt with in presidential addresses and papers presented to the various Sections, may perhaps be doubted; but even if the mental grasp be weak and the picture induced be primitive, the mere existence of a respectful attitude and receptive mind towards scientific studies is not to be despised.

In the main, of course, the Association is an assembly of scientific workers, most of whom have no wish to discourse to the laity and no capacity for transforming the special vocabularies of their subjects into the simpler—not to say sensational—forms required by many general readers. It ought to be gratefully recognised, however, that the lay writer who is sufficiently well informed to be able to present a scientific subject in attractive literary style, and accurately as well, is performing a useful purpose for science. The investigator who can do this for advances to which he has himself contributed, and on which he is an authority, can always find a generous welcome on platform or in the periodical press, but it is rarely that the faculties of research and exposition are so closely combined; and it may be just as well that they are usually separated. The first business of the man of science is to discover—to add to the sum of natural knowledge; and if he describes his work clearly and in terms which are intelligible to other investigators, he has done his part. It is really supererogatory for him to take up the task of enlightening—or entertaining—a public unfamiliar with even the alphabet of the language of the branch of science in which he works. He may be able to interest members of the British Association, because most of them are engaged in scientific work of one kind or another, and the rest scarcely expect to listen to childish discourses; but the crowd in the street is not within his ambit. The active scientific investigator might appropriately apply to those outside his gates the words, "I have yet many things to say unto you, but ye cannot bear them now." Science does not need to be sought with a contrite

heart, but it does demand a certain amount of preparation from all who would understand the full meaning of the treasures within its temples.

So far as it is possible for men of science to offer popular expositions of subjects on which they are creative authorities, this is done in the Citizens Lectures now delivered at each meeting of the British Association and on a more extended scale than usual at this year's meeting. These lectures are not intended for members of the Association but for the general public, and the large audiences which attend them show that very many people are interested in simple accounts of scientific work and progress in certain fields. Such descriptive lectures, however, do little more than titillate the minds of most of the hearers, and nothing to impress them with the conviction that science is the greatest social factor in modern civilisation. Wonder may be excited by experiment and exposition, but it needs to be associated with confidence in the guidance which science can give if our social and industrial conditions are to derive the best advantages from progressive knowledge. At least one of these public lectures should be devoted each year to the advocacy of science and scientific methods in national affairs, instead of making them all informative displays of achievements in selected fields.

Outside the Section rooms (where scientific workers may be permitted to use their own forms of technical expression) and beyond the lecture halls (where experienced speakers successfully hold the attention of assemblies of citizens) is the general public as a whole, reading the daily and weekly newspapers and expecting to be informed in its own language of important scientific developments of all kinds, however intricate they may be—as, for example, the constitution of the atom, the quantum theory, the principle of relativity, or the significance of cell structure. To provide this great group with the pabulum it is capable of digesting is a task which most research workers prefer to leave to others; and rightly so. Good service is, however, rendered to science by writers who can present difficult subjects in attractive literary form without departing essentially from permissible limits of accuracy—large though these may seem to be to precise investigators. There are such contributors to the general periodical press, and we think that every encouragement and assistance should be given to them. The more that the public is made to understand the fertility and the power of science the greater will be the trust in scientific service, and provision for scientific study and research will be correspondingly increased.

In the British Isles, little attempt has been made to secure wide publicity for scientific institutions and work, with the result that they are almost unknown outside scientific circles. The publications of the National Physical Laboratory, for example, are altogether inadequate to give even industrialists an idea of the work carried on in that institution. On the other hand, the U.S. Bureau of Standards issues frequent Bulletins dealing broadly with topics in which practical men are interested and in which developments have recently taken place. The U.S. National Research Council also publishes a number of useful Bulletins surveying the state of knowledge of various scientific subjects and bringing together important data. No institution or society in the British Isles issues anything comparable with these Bulletins: most of them seem, indeed, to be content to hide their light under a bushel, so far as the outside world is concerned, and to discourage any attempts made to extend the zone of illumination.

We do not suggest that scientific and technical societies should add a publicity service to their functions: they are primarily intended for the reception and discussion of new contributions to knowledge, and their concern is the interests of their fellows rather than the attention of the public. The British Association is on a different footing, in that no technical qualification is required for membership and that it sets out deliberately to create interest in science in the centres where the annual meetings are held, and beyond them by the reports of its proceedings. The presidential addresses, published annually for the Association by Mr. John Murray under the title "The Advancement of Science" (price 6*s*.), though often somewhat special in style and scope, constitute the best annual record of the position of scientific subjects of prime importance. Probably few men of science are capable of following intelligently all the subjects reviewed in these addresses, and the general public may therefore be pardoned for not comprehending most of them. To students of science, however, whether as a professional occupation or as a leisure hour pursuit, the addresses are invaluable as authoritative statements of scientific fact and theory, and the volumes containing them should be in the library of every one who finds satisfaction in pondering over the great problems with which modern science deals.

Though the British Association welcomes membership from the general public, it is not too much to say that the presidential addresses, and most of the papers presented to Sections, are intended for audiences of special scientific workers. In the case of a body like the British Medical Association, membership is limited to professionally qualified men, and in the Sections, therefore, no attempt need be made to deal with scientific subjects in popular terms. With its mixed membership, however, the British Association is in a

different—and also more difficult—position. Interpreters are needed, if not in the Section rooms themselves, then in the public press. Leading newspapers prefer that their own correspondents or contributors should perform this function, but there are many others which would gladly make use of notes and articles on scientific subjects suitable for the general reading public.

In the United States an institution entitled "Science Service" was established a year or so ago to provide such popular articles as a scientific news syndicate, and it now supplies about fifty American newspapers, and several in Canada and other parts of the world, with news Bulletins sent from Washington every day except Sunday. "The first consideration in a Bulletin story," says a circular of instruction to writers of articles, "is to tell of or interpret a scientific event. But the news stories must be so well written that large national newspapers will use them without rewriting or revision, either in form or language. Write your story so that those who know nothing about science will understand and want to read it. Weave in the scientific background that the man in the street does not have. Use simple words. Make your story as graphic as if you were talking about it." It is pointed out, in addition, that "'By Science Service' must stand for accuracy of content and implication."

In order to establish this publicity agency for science, a generous benefactor gave the sum of one million dollars to a Board of Trustees which includes among its members several of the most distinguished men of science in the United States. The whole field of scientific activity everywhere is covered by "Science Service," and the Bulletins are first-rate examples of what can be done to present scientific progress in popular and yet accurate form. We understand that the demand for the Bulletins from newspapers is now sufficient to make this admirable news agency practically self-supporting.

Here, then, we have an excellent example of what can be done successfully for the popularisation of science; and it is obvious that the constitution and methods of such an organisation are very different from those of the British Association, though the aims of both are "to promote general interest in science and its applications." We believe that the National Union of Scientific Workers contemplates establishing a similar scientific news agency to that of "Science Service," and a beginning has already been made by the British Science Guild by the issue of Publicity Pamphlets sent to the newspaper press for reproduction in whole or in part without payment. Since January 1921, the Engineering Foundation of New York has been issuing a series of such "Research Narratives," each containing the story of some research, discovery, or notable achievement in science or engineering. In one form or another these narratives have found their way through practically the entire range of the public press in America as well as the technical journals.

It is clear, therefore, that we in the British Isles are much behind the United States in the provision made for publicity for science. Our scientific societies are second to none, and the number and value of papers published by them are higher now than ever they were, yet no adequate agency exists to extend the knowledge of this work beyond scientific circles and thus to create in the public mind a feeling of pride in our scientific achievements. A great opportunity awaits the benefactor who will provide a liberal sum to establish a British science publicity service comparable with what has proved so effective in America. Political, social, religious, temperance, labour, and scores of other organisations regard it as a duty to carry on their propaganda by means of leaflets and like publications, but science is content to keep its message to itself. It is no wonder, therefore, that the community understands so little of the value and meaning of science. Let us hope that means will soon be forthcoming to establish a bureau which will not only make the proceedings of annual meetings of the British Association widely known and easily intelligible, but will also, throughout the year, continue to interpret scientific advances to a world eager to learn of them but unacquainted with the technical vocabularies in which they are commonly expressed.

Science and Man.

Science and Civilization. Essays arranged and edited by F. S. Marvin. (The Unity Series, VI.) Pp. 350. (London: Oxford University Press, 1923.) 12*s.* 6*d.* net.

THE history of science is by no means a record of steady progress. It was born among the Ionian Greeks, who were the first to speculate intelligently, on the basis of observed facts, "how things grow" and "how they behave," these being the meanings of their two words *physis* and *nomos*, so inadequately represented by *natura* and *lex*. It is often said that Greek science was unsound, being based on brilliant guesswork instead of careful investigation. The Greeks certainly loved bold and sweeping generalisations, but modern biologists, including Charles Darwin, have thought no praise too high for Aristotle, and the achievements of Greece in mathematics, astronomy, and medicine are now held to be scarcely less notable. It must, however, be admitted that the

ancients were handicapped by the want of scientific instruments, and that their backwardness in invention was partly due to an erroneous standard of values. If European nations still think it a finer thing to be an orator than a scientific inventor, that is a prejudice which we owe to the Greeks.

The Roman "steam-roller" was not favourable to originality and intellectual progress. After Galen (about A.D. 200) a Sahara of scientific barrenness begins, a dreary waste from which European history emerges only in the sixteenth century. Neither Hellenistic philosophy nor Catholic Christianity did anything to stop this barbarisation, the inevitable result of the long orgy of superstition, massacre, and pillage which we call the Dark Ages. Mankind cannot afford to forget that a measure of stability in political and social conditions is necessary not only for progress but also for the preservation of the gains of the past. The seven hundred years which followed the break-up of the Western Empire might have been blotted out of history without any great loss.

The greater part of Mr. Marvin's excellent volume of essays is devoted to modern problems. The writers admit frankly that the materialistic trend of science in the nineteenth century was the result of its unequal development. Biology advanced more quickly than psychology, and the sciences of inorganic nature were ahead of biology. The tendency to reduce life to mechanism is being abandoned in response to protests from science itself, and the problems of conscious life are seen to involve metaphysical questions with which the older generation hoped to dispense.

Prof. Whitehead, as is well known, thinks that the theories of Einstein will have a revolutionary effect on our conceptions of space and time. "The whole synthesis of the seventeenth century has to be recast. Its time, its space, and its matter are in the melting-pot—and there we must leave them." It will take many years before this judgment can be either affirmed with confidence or denied. There is reason to think that at present Continental thinkers are not prepared to go quite so far as Prof. Whitehead and his friends. There is no doubt that Einstein has made a great mathematical discovery; but we may be permitted to doubt whether a mathematical discovery is likely to give us a new philosophy.

Prof. Arthur Thomson deals judiciously with post-Darwinian biology, and does not talk, as some are rashly doing, about "the abandonment of natural selection." But I cannot agree with him when he says that "no conflict should be possible between religion and science, unless we try to speak two languages at once," or that "scientific and religious concepts are incommensurable." The assumption which underlies such statements is that science deals with facts and religion with values, and that it is possible to keep these two aspects of reality apart. I maintain, on the contrary, that a fact without value is no fact, and a value without fact no value. The two cannot be separated, and the salutary rivalry of scientific and religious truth must continue as long as men take both seriously. It will not do for science to say to religion, "Leave me alone and I will leave you alone."

Mr. Julian Huxley's long essay on science and religion takes a different line. It is interesting not only for the discussion on the place which science can find for the conception of God, but for the confident tone in which the author declares his conviction that the organic is evolved from the inorganic, through the development of colloids from smaller molecules. "Thus the forms of life, simple at first, attained progressively to greater complexity; mind, negligible in the lower forms, became of greater and greater importance, until it reached its present level in man." Mr. Huxley would not maintain that this theory has been demonstrated; but it seems probable that the monistic view of the structure of the universe will in time be generally accepted. The alternative theory that animated spores came to the earth from other bodies gives no explanation of the origin of life, and has difficulties of its own.

I am less satisfied with this writer's attempt to justify a theistic philosophy by setting the progress which he finds to be the law of organic evolution against the pessimistic conclusion based on the second law of thermodynamics. For even if we assume that increasing complexity in living organisms carries with it increasing value, the phase of evolution through which life on this planet is passing is but a transitory episode, which will probably be followed by a reverse process of involution, when our globe becomes less favourable to the higher forms of life. In any case, planetary progress can be only a backwash in the universal current which, if the aforesaid law is true, is carrying all matter towards immobility and final death. No satisfying theism can be erected on this basis. It would surely be better to assume that whatever power wound up the clock once can wind it up again, and that the life of the universe is perpetual, as its Creator is eternal. We are then free to believe in a God whose being is above the recurrent births and deaths of stellar systems.

Mr. Marvin, however, pins his faith on progress in time, and ends the book with a characteristic editorial chirp. It is probably true, as he says, that humanity is still young, and capable of achievements still undreamed of. Hope for the future is reasonable, so long as we do not make a religion of it.

W. R. INGE.

The Manufacture of Acids and Alkalis.

The Manufacture of Acids and Alkalis. By Prof. George Lunge. Completely revised and rewritten under the Editorship of Dr. A. C. Cumming. Vol. 1: *Raw Materials for the Manufacture of Sulphuric Acid and the Manufacture of Sulphur Dioxide.* By W. Wyld. Pp. xiii+558. 36*s.* net. Vol. 5: *The Manufacture of Hydrochloric Acid and Saltcake.* By Dr. A. C. Cumming. Pp. xv+423. 31*s.* 6*d.* net. (London and Edinburgh: Gurney and Jackson, 1923.)

THE various treatises on different departments of applied chemistry which chemical literature owes to the genius and industry of the late Prof. Lunge are among the classics of chemical technology. They have passed through many editions in fairly quick succession, and their betterment and revision was the constant employment of their author's leisure, no pains being spared by him to make them an accurate and faithful reflex of the state of contemporary knowledge of the several subjects with which they were concerned. Prof. Lunge enjoyed many opportunities and facilities to this end. As professor of applied chemistry in the Zurich Polytechnic, one of the best equipped and most famous schools of chemical technology in the world, he was an acknowledged authority on many branches of manufacturing chemistry, and particularly on the special branches dealt with in the books under review. The manufacture of acids and alkali was in fact the chief chemical industry in which Dr. Lunge was employed during his sojourn in England and before his appointment to the distinguished position he occupied until his death. A brief account of his life and work appeared in NATURE of February 17, p. 228.

These treatises constitute, in the aggregate, a valuable literary property, and the publishers are well advised in seeking to maintain the reputation they have hitherto enjoyed as faithful and accurate accounts of the state of contemporary procedure in the special branches of chemical industry with which they deal, by entrusting their revision to competent authorities, and in issuing new editions at comparatively short intervals.

It might be thought that in the case of an industry so well established as that of the manufacture of alkali and of the industries which are so closely associated with it, the last word had been said in respect to processes and procedure. Such, however, is very far from being the case, as even a very superficial comparison of successive editions of these treatises will make manifest. The changes may not in all cases be fundamental or subversive, but they are more or less important as tending to efficiency and economy, and no account of the contemporary condition of the manufacture would be adequate without reference to them.

The general superintendence and editorship of the new editions of these manuals has been entrusted to the competent hands of Dr. A. C. Cumming, under whose direction they have been completely revised and rewritten. The volume on raw materials for the manufacture of sulphuric acid and of sulphur dioxide has been assigned to Mr. Wilfrid Wyld, who has been associated with important concerns in Yorkshire and elsewhere, and brings to his task the fruits of a large experience.

In a general preface prefixed to the several volumes Dr. Cumming has given a brief account of the history and development of the late Prof. Lunge's literary labours in connexion with applied chemistry, which is of interest as showing how the scope of these labours was gradually enlarged so that it became practically an encyclopedia of the many chemical industries. The first English edition of the volume on sulphuric acid appeared in 1879, and the last edition in 1913. This was followed in 1917 by a supplementary volume on sulphuric and nitric acids. This was the last of Lunge's contributions to this special field of chemical technology.

The book under review shows no very striking features in the way of new developments. As regards raw materials, the most important change is the revolution in the production of commercial sulphur effected by the Frasch process. This remarkable process is one of the most notable chemical engineering triumphs of the present century. In 1869 an enormous deposit of sulphur was discovered in Louisiana in the course of well-sinking in connexion with petroleum, but all attempts to work this deposit commercially failed until the genius of Herman Frasch devised the method associated with his name. Space will not allow of any detailed description of the process. Briefly, the method consists in sending down a sufficiency of superheated water and thus melting out the sulphur, which liquefies at about 116°, from the pockets in the limestone and beds of gypsum in which it occurs. The molten sulphur is then forced to the surface by means of compressed air, and of course consolidates as it cools. The book contains a fairly full account of this process, which is now worked on a very considerable scale, not only in Louisiana but also in Texas, where similar sulphur deposits have been found to occur. It has rendered America independent of all outside sources of sulphur supply, and for a time seriously threatened the existence of the Sicilian industry, of which it has destroyed the monopoly.

Mr. Wyld's account of the history of the process and of its successive developments leaves nothing to be desired in point of accuracy and completeness. It forms indeed a most interesting section of the chapter devoted to the exploitation of the natural deposits of sulphur which occur in various parts of the world.

The book, of course, deals with a great variety of processes for obtaining sulphur: from raw ores; from spent oxide in the manufacture of coal-gas; from pyrites; from sulphur dioxide, as from smeltery fumes; from sulphuretted hydrogen and sulphites and sulphides and from sulphates of the alkaline earths. These last-named processes became of the utmost importance to Germany during the War, owing to her inability to import sulphur or any considerable supply of pyrites. History affords many instances where a nation or manufacturing community under the stress of necessity, often occasioned by war, has been compelled to adopt new methods or to modify existing ones, and such modifications have frequently taken a permanent place in industry. What, however, is to be the ultimate fate of the processes which Germany was compelled to adopt remains to be determined. Certain of them have been found to be economically unsound when compared with pre-War methods, and have already been given up, but their story is interesting as a chapter in industrial progress and as showing what knowledge, skill, resourcefulness, energy, and application will achieve in overcoming obstacles which at first sight seemed well-nigh insuperable.

In an industry such as that described in this book analytical control is frequently of the utmost importance, but it is too often neglected, or only inadequately carried out, owing, in many cases, to the want of suitable methods or to the time required to make the results available to the management.

A commendable feature in the book is the space allotted to descriptions of the most suitable analytical methods at the disposal of the works chemist. The treatise in this respect becomes a veritable *vade mecum*, and should be indispensable to every well-ordered factory. The improvement of analytical processes applicable to the conditions of chemical works was a constant problem with the late director of the chemical department of the Zurich Polytechnic, and certain of the methods described in this book are the outcome of investigations made by him in conjunction with his senior pupils.

The various forms of pyrites, brimstone, and spent oxide are the usual sources of sulphur dioxide, mainly as an " intermediate " in the manufacture of sulphuric acid. For small-scale operations sulphur dioxide is made by heating charcoal or sulphur with sulphuric acid, usually of 74 per cent. SO_3 or 165° Tw. As the gas is easily liquefied, the temperature of a mixture of snow or powdered ice and salt being sufficient to effect its condensation, it may be preserved as a liquid in ordinary soda-water syphons, whence the liquid or the gas may be liberated as desired. This section of the book contains a full account of the physical and chemical properties of this compound, the modes of its detection and estimation, and of its employment in the manufacture of wood pulp and as a disinfecting and antiseptic agent and also as a bleaching agent, especially for wool, silk, straw, etc., and to a limited extent in wine-making in the form of meta bisulphite. Other sulphur compounds of which full and accurate accounts are given are sulphur trioxide and the various nitrogen-sulphur compounds. Indeed, the chemical history of the various sulphur compounds, so far as these have any relation to sulphuric acid and its manufacture, may be said to be accurate and complete.

As regards the actual manufacture of sulphuric acid, a comparison with the accounts given in the earlier editions shows what the influence of the War has been on the production of this important chemical. Pre-War plant was found to be utterly inadequate to meet the demand for this acid, as incidentally required in the manufacture of munitions, and, as is well known, it was necessary to make special arrangements to this end. Some account is given of the means installed at Queen's Ferry and other places. The section on burners for sulphur and on the plant needed in connexion with the use of pyrites has been carefully revised and brought up-to-date, and constitutes one of the most valuable sections of the work.

The volume on the manufacture of hydrochloric acid and salt-cake exhibits, perhaps in a more striking manner, the changes, almost revolutionary in character, which have overtaken this special branch of the alkali manufacture. The Hargreaves' process is no longer in operation in this country. Pan and furnace methods are still worked, but with the gradual disappearance of the Leblanc process it may be anticipated they will give way to one or other of the more modern processes described in this volume.

As the editor points out, the manufacture of hydrochloric acid is no longer necessarily connected with the manufacture of salt-cake, and fuller treatment has therefore been given to its manufacture from chlorine and to other modern developments.

The revised work is a most valuable addition to the literature of one of our staple industries, and the editor is to be congratulated on the care and thoroughness with which he has completed his task.

T. E. THORPE.

National Eugenics.

(1) *Eugenical Sterilisation in the United States.* By Dr. H. H. Laughlin. Pp. xxiii+502. (Chicago: Psychopathic Laboratory of the Municipal Court of Chicago, 1922.) n.p.

(2) *Eugénique et sélection.* Par E. Apert, L. Cuénot, Le Major Darwin, F. Houssay, L. March, G. Papillaut, Ed. Perrier, Ch. Richet, G. Schreiber. (Bibliothèque générale des Sciences sociales.) Pp. iii+248. (Paris: F. Alcan, 1922.) 15 francs net.

"NATIONAL Eugenics is the study of those agencies under social control which may improve or impair the racial qualities of future generations." Galton thus linked the word "national" to eugenics. The problem in its fundamental biological aspects is in one sense the same for all nations, but to each nation it may present different sides and provoke different methods of attack, if indeed it is attacked at all. The experiences of one nation are, nevertheless, worthy of observation by all.

(1) From this point of view, the first part of Dr. Laughlin's book is of interest. This part consists of a detailed analysis, written from a lawyer's point of view, of the sterilisation laws enacted in the United States prior to January 1, 1922, with summaries of the extent to which they have been put into practice in different States and a full account of the litigation arising out of them. Fifteen States have had, and nine still have, sterilisation laws, some mandatory and some optional. The scope of these laws varies from State to State, but in no case extends beyond certain inmates of State, county, or municipal institutions. The consent of the relatives has in general been easily obtained. There is very great variation in the opinions quoted of the executive boards and superintendents, and consequently in the extent to which the laws have been put into practice.

From 1907 until January 1, 1921, 3233 operations in all were carried out under the laws, and of these 2558 occurred in California (1009 being due to a single institution). Nebraska comes next with 155 cases. In Wisconsin, Connecticut, and North Dakota the law is still being applied, but to a very limited extent. In Washington, where the object is purely punitive, only one case has so far occurred. In six of the fifteen States the law has been repealed or vetoed, and in three it has become a dead letter. In test cases, violation of the State or Federal constitution has been argued chiefly on the grounds of class legislation, cruel or unusual punishment, or denial of equal protection of the laws. In five States the courts have held the sterilisation laws unconstitutional, but the quoted opinion of various American legal experts differs more on their expediency than on their constitutionality. The history of the working of these laws indicates that, in the country as a whole, public opinion is not at present behind them.

As an exhaustive historical record and guide to existing practice in the United States this compilation will no doubt prove a useful book of reference for those practically concerned with sterilisation in the legislative, legal, and administrative fields. As a contribution to the scientific discussion of the social and biological aspects of the problem it has less weight. The section on eugenical diagnosis is intended "to serve the legislator in his efforts to weigh the matter in its entirety." It is not easy to see, however, that this purpose can be achieved by the somewhat crude and uncritical summary offered of Mendelian theory and its application. The student will find the book overloaded with detail (incidentally there are discrepancies between text and table in the indentification numbers of individuals in the case pedigrees), but it contains a great deal of information, not easily accessible hitherto, of which the eugenist should not be ignorant.

(2) "Eugénique et sélection" is a collection of papers, most of which were delivered as lectures during 1920–21 at the meetings of the "Société française d'Eugénique," and are devoted mainly to a discussion of the consequences of the War in France from a eugenical point of view. It includes an earlier paper by the late vice-president of the Society, Frederic Houssay, in which, starting from a series of experiments on six generations of hens, he argues that there is a degeneracy of those in easy circumstances due to the abuse of food, each generation poisoning the next through toxic excretions into the germ cells.

Dr. Apert deals with the effect of the War on the health of the French nation. The two chief qualitative results he finds are an increased tendency to tuberculosis and the expectation of a series of infantile generations of lessened resistance to disease. To these he adds alcoholism and syphilis as active menaces to the French race. M. Lucien March treats the question from a quantitative aspect. He estimates the total loss of population to France (including the deficit of births) directly due to the War as 3,000,000 people. He examines the size of family in various classes, and gives as the three fundamental factors on which the birth-rate depends: (1) the cost of the child before he is self-supporting; (2) the chance the child has of maintaining himself in at least as good circumstances as his parents; and (3) the opinion that the parents hold of (1) and (2). He outlines the various steps taken in France to encourage natality, among which may be noted the existence of more than 70 employers' associations which give benefits for each

child of an employee, but safeguard at the same time against preferential employment of single men by basing each employer's contribution on the total salaries paid by him. None of these measures are contrary to eugenical principles; they are, however, aimed directly at quantity instead of quality. From the psycho-social aspect and a consideration of the statistics of insanity and suicide Dr. Papillaut finds in the War confirmatory evidence of the predominant effect of heredity over environment. War effect on marriages is discussed by Dr. G. Schreiber. He regards the mixed marriages of French women with men of other Allied nationalities as a probable benefit to the French nation. He urges the establishment of a medical examination before marriage that shall be compulsory but carry no legal sanction.

The volume closes with an address on some zoological aspects of eugenics delivered by M. Lucien Cuénot at the second National Congress of Eugenics in 1921. Starting from the Mendelian conception of unit factors susceptible of mutations which appear as somatic changes, he discusses the position of Mendelists with reference to the heredity of acquired characters and the origin of adaptations. On the first question the author retains an open mind in the light of Guyer and Smith's experiments on the inheritance of acquired eye defect in rabbits. He puts the case well for preadaptation—*i.e.* the surroundings as a consequence of the structures with which the animal is born and not *vice versa*—and reviews the difficulties of interpretation of the mechanical perfection of certain structures in relation to their apparently small utility. Such difficulties lead him to feel that there is something wanting in the conception of evolution, some general law that has still to be discovered.

A collection such as this, which treats the subject from so many points of view, can do no more than touch the surface, but it is well adapted to fulfil its aim of giving the French-speaking public an idea of the object and extent of the science of eugenics as defined by Galton.

The Animal Parasites of Man.

Animal Parasites and Human Disease. By Dr. Asa C. Chandler. Second edition, revised. Pp. xiii+572. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 22*s.* net.

IT is unfortunate that animal parasitology, the youngest branch of preventive medicine, is still regarded by many people as a field of knowledge that is of little moment outside tropical and subtropical regions. Everybody acknowledges the direct connexion with man's welfare of the parasites dealt with in the sister science of bacteriology; but the parasitic protozoa, helminths and arthropods, which are responsible for so much human suffering, are scarcely thought of by the general public. Indeed, even the average physician of temperate climates seems to be satisfied to have quite a superficial knowledge of this branch of his profession; yet these parasites, which are concerned with the most varied diseases and morbid conditions, have been found to be widespread and in abundance, wherever they have been looked for. There are many popular books on the animal parasites of economic importance, but remarkably few on those which affect human health. It is admittedly very difficult to write an attractive book, in popular language, on any scientific subject, and when the book deals with such objects as tapeworms, fleas, and lice, the general reader is apt to put it aside with a faint feeling of disgust. But among these and other such despised creatures are many the life histories of which are of much interest, and on account of the practical importance of their relations to man, they should claim the attention of all.

Dr. Chandler describes his book as a compilation, but it is more than that: the subject is presented in a fresh and interesting manner, and the book shows evidence of much care and skill in the selection of its contents. The information given has been brought thoroughly up-to-date, and all recent work of any importance is referred to. A sufficient account is given of the spirochætes, which the author considers to be "on the vague unsettled border-line between bacteria and protozoa." Many, perhaps, would be inclined to adopt a more critical attitude towards the phenomenon of "granule shedding" in these organisms. The subject of the prevention of syphilis is discussed in a broad and logical spirit. The leishmania bodies, trypanosomes, intestinal flagellates, and amœbæ are well described, and there are short accounts of the diseases to which they give rise. The author seems to accept without demur the parasite recently described by Kofoid and Swezy, and named by them *Councilmania lafleuri*. The parasitology of malaria is adequately dealt with, and the Rickettsia organisms are alluded to. The life history of the liver fluke is told at length, and illustrations and descriptions are given of the other trematodes which occur as human parasites. The "worms" are all figured, and the salient points of their bionomics mentioned. Ten pages are devoted to *Trichinella spiralis*, and about as many to the various species of Filaria. The rest of the book, about two hundred pages, is concerned with the arthropoda. The entomological section is particularly good, and contains an excellent account of the habits and distribution of those insects which are harmful to man.

Throughout the book, adequate reference is made to the diseases caused by animal parasites, and to the methods employed for controlling the latter. With a few exceptions, the illustrations are good, and they possess the commendable feature that, where the organism is not drawn of the actual size, the magnification used is always indicated.

It is to be hoped that this excellent book will help to arouse a more general interest in a subject with which all are personally concerned. Although it is written in a popular style, the book is always accurate; any one who reads it carefully will acquire the foundation of a good general knowledge of the animal parasites of man, and, if he wishes to pursue the subject further, he will find that he has nothing to unlearn.

H. J. Walton.

Our Bookshelf.

Spezieller Kanon der zentralen Sonnen- und Mondfinsternisse, welche innerhalb des Zeitraums von 600 *bis* 1800 *N. Chr. in Europa sichtbar waren.* Von J. Fr. Schroeter. Pp. xxiv + 305 + cl Tafeln. (Kristiania: Jacob Dybwad, 1923.)

In this volume Schroeter continues Ginzel's "Spezieller Kanon der Sonnen- und Mondfinsternisse" (1899), which contained all eclipses visible in an area between 10° W. and 50° E. of Greenwich, and between 30° and 50° N. latitude, from 900 B.C. to A.D. 600. Schroeter's scope is somewhat different. He gives all central eclipses of the sun and all total eclipses of the moon visible in Europe between A.D. 600 and 1800. For partial eclipses of the moon between those dates it is still necessary to turn to Oppolzer. It will be observed that the area covered by Schroeter differs widely from that covered by Ginzel, and results from the substitution of a European for a Mediterranean civilisation. One result of this selection is that the present volume is of little use for the study of the numerous eclipses recorded in the history of non-European countries. Perhaps some day each continent will have its own equivalent to Schroeter.

The elements of eclipses used in this volume are based on the same constants and computed by the same formulæ as those determined by Ginzel and used in his "Spezieller Kanon," but the errors attaching to the results are far less at the dates for which these tables are constructed than for the distant dates with which Ginzel deals. One advantage of Schroeter's volume over Ginzel's is that, while an exact computation from Ginzel's elements can only be made by reference to the formulæ contained in Oppolzer's "Canon der Finsternisse," Schroeter prints these formulæ in his introduction. Another difference is that where Ginzel contents himself with computing the northern and southern limits of the total or annular phase of a solar eclipse, Schroeter computes also the curves of nine digits magnitude. Again, while Ginzel has one large-scale map showing all the zones of total and annular eclipses for each century, Schroeter, though limiting himself to a smaller scale, has a separate map for each eclipse. There is, however, nothing in Schroeter to correspond to the detailed discussion of each historical eclipse which is one of the most valuable features of Ginzel's work.

This work is likely to be of more use for historical than for astronomical studies. Probably it will be used mainly by those astronomers who may be called upon to assist students of history.

Modern Gas Producers. By N. E. Rambush. Pp. xix + 545. (London: Benn Bros., Ltd., 1923.) 55*s*. net.

We have nothing but commendation for this treatise on modern gas producers. It is a finely conceived work admirably executed. The author is one of the few equipped with theoretical knowledge of the thermal processes involved in producer gas manufacture, and with the extensive acquaintance with technological aspects of the matter required for an adequate treatment of the subject. Of this, the work before us is sufficient witness. Four sections devoted respectively to (1) the theory of the formation of producer gas, (2) types of gas producers, (3) control and operating principles of producer gas plants, and (4) the utilisation of producer gas, are comprised in the book. The theory of the subject is developed in an extremely clear manner. We think the author has succeeded in his declared endeavour to describe plants and types of producers quite impartially. A rather careful reading of the work has left us quite undecided as to what plants the author has been personally connected with in a professional capacity. This is eminently desirable in a work of this nature, and in marked contrast to what we have found in at least one volume of the present series of publications. Specific features of design commonly employed in practice and of a number of special designs are set out in considerable detail. This section might easily have degenerated, as has happened in too many cases recently, into a highly priced trade circular. It has not done so, but is extremely readable and informative, and contains much valuable data relating to actual trials of the various plants. The third section is commendably brief, as fuller particulars of the testing of fuel and gas are contained in another volume of the same series. Typical applications of producer gas in the gas engine, gas turbine, furnaces, etc., and the relative efficiencies in use of various grades of gas, are briefly treated in the last section.

The work is characterised by a number of extremely valuable tables and graphs facilitating calculation. There are altogether 356 drawings and illustrations, all beautifully executed and reproduced. An adequate index is provided. We think the high price of the volume justifiable, and prophesy an assured premier position for the work in the literature of producer gas technology.

Department of Scientific and Industrial Research. Report of the Fuel Research Board for the Years 1922, 1923. First Section: The Production of Air-dried Peat. Pp. vii + 146. (London: H.M. Stationery Office, 1923.) 5*s*. net.

Mechanical methods of winning peat in operation in Europe and Canada are dealt with in this report, in which are discussed the difficulties encountered in winning the air-dried fuel, and possible schemes for

winning it on a very large scale. It describes also the investigations on the winning and the utilisation of peat undertaken by the Fuel Research Board during the past four or five years. These investigations were the preparation of air-dried machine peat in an Irish bog, but by well-known Continental methods and on a very small scale, together with the establishment of the facts, long known abroad, that machine peat dries more uniformly than slane-cut peat, and has a higher value than slane-cut peat of the same calorific power.

The report is disappointing inasmuch as it shows that the Fuel Research Board has not made any serious attempt to grapple with the problems of the winning and the utilisation of peat. On the other hand, it is valuable since it shows that several attempts to solve these problems are being made in Germany, Sweden, Russia, and Canada. Prof. Purcell's detailed and critical descriptions of the peat industries of northern Germany, Sweden, and Canada are interesting and instructive. One would have expected, however, that the Fuel Research Board's contribution to the solution of these problems during the past four or five years would have been considerably more than a full description of what other and poorer countries are doing in regard to these important matters. HUGH RYAN.

El Arte de los Metales (Metallurgy). Translated from the Spanish of Alvaro Alonzo Barba, by Ross E. Douglass and E. P. Mathewson. Pp. ix + 288. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1923.) 17*s.* 6*d.* net.

THE earliest known work on American metallurgy was written by Alvaro Alonzo Barba, a priest of Potosi in Bolivia, and was published in Spain in 1640 and several times reprinted. This book, of great historical interest, has now been fully translated by two American metallurgists, and forms an important technological document. The most valuable feature of the work is its detailed description of the methods of extracting silver from its ores practised in Bolivia, a region in which metallurgical skill had at that time attained to a very high level. Amalgamation and the processes connected with it are here described minutely, and in a straightforward fashion, with simple diagrams. Barba was not a profound thinker, and accepted the current superstitions regarding ores and minerals without question, comparing in this respect very unfavourably with his great predecessor Agricola; but his shrewdness in practical matters and his close acquaintance with the work of smelting and extraction on a large scale are evident throughout. The translation, except for a few explanations of technical terms, inserted in brackets, is not annotated, so that the student will do well to read it in conjunction with Hoover's remarkable translation of Agricola, with its abundant historical notes. C. H. D.

An Introduction to Stratigraphy (British Isles). By Dr. L. D. Stamp. Pp. xv + 368. (London: T. Murby and Co., 1923.) 10*s.* net.

THIS is a distinctly original work that will be of service to very many students who are unable to follow current literature as it appears. Dr. Stamp brings together, with good references, results recently obtained by others, but adds to them by his personal knowledge and his methods of appreciation. Sections showing the mode of deposition of various series, and sketch-maps of their distribution, give unusual interest to what might have been a mere description of the part played by each formation in the structure of the British Isles. As examples, we may take the general map and the small local section (pp. 146 and 147) dealing with the Millstone Grit, and the suggestive map (p. 170) of Britain in the Permian period, with its stream-notched uplands supplying material to the basins in the midlands and the south. Not content, the author gives us an enlarged detail of the Cornubian area on p. 175. Dr. Stamp (p. 241) is not so bold as Mr. E. Greenly in carrying his Cretaceous strata across the peneplane of Snowdonia. He writes throughout, in spite of very concise limits, as if he were actually viewing from an aeroplane the geographic features of the past. G. A. J. C.

Primitive Tider i Norge: En oversigt over stenalderen. Av Haakon Shetelig. Pp. iv + 380. (Bergen: John Griegs Forlag, 1922.) n.p.

DR. SHETELIG, in his introduction, points out that in few countries in Europe does written history begin at so late a date as in Norway. This gives to the study of prehistoric antiquities in that country a position of peculiar importance. For archæologists generally the prehistory of the area of which Norway forms a part is also of particular interest, especially in its earlier stages, in view of its relation to that of the rest of Europe; it is there that we find the evidence for the earliest stages of neolithic culture. On both accounts, therefore, Dr. Shetelig's study of the Stone Age in Norway is welcome. For students outside his own country its value will lie largely in the author's survey of the latest views of Norwegian men of science on Scandinavian archæology and the relations of Norway in the Stone Age to the rest of this area. From this point of view his chapters on the first appearance of man in Norway, the transition to the New Stone Age, and the kitchen-middens are particularly worthy of note, as also is his account of Stone Age art, the trade in amber, and the use of jade.. The book is fully and admirably illustrated.

How to Paint Permanent Pictures. By Prof. M. Toch. Pp. 105. (London: Scott, Greenwood and Son; New York: D. Van Nostrand and Co., 1922.) 7*s.* 6*d.* net.

THE reviewer has often wondered, when looking at paintings of great merit which are gradually fading away or cracking in pieces, why artists do not spend a little time in learning something about their materials. In many cases they are probably at the mercy of the dealers. It would seem desirable, therefore, to direct attention to this small book by Dr. Toch, which deals with the properties of pigments simply yet scientifically, and should be valuable to all who paint pictures. In it are described those colours which are permanent and those which may be expected to fade away more or less completely with lapse of time. Varnishes are also discussed.

Letters to the Editor.

The Inheritance of Acquired Characters in Alytes.

FOR those who are not concerned with the details of this debate I suppose that the critical sentence in Dr. Kammerer's letter (NATURE, August 18) is that in which he expresses himself as follows: "I willingly admit that the traditional explanation of the pads, namely, that they are produced by friction with the skin of the female, may possibly be a fable," adding references to passages in which he had already discussed alternative hypotheses. But those alternatives were ultimately rejected, and his final judgment was that until the assumption that the pads arise through functional adaptation can be replaced by a better, it remains the only acceptable account.[1] Remarking that the alleged nuptial pads may possibly be due directly to life in water and not an adaptative response, he now tells us that the relevance of his observation to the theory of heredity is in either alternative the same But is it?

The heavy task of searching for evidence of hereditary transmission of acquired characters has clearly been undertaken in the single hope, forlorn indeed, but undying, that the difficulty created by the existence of the *adaptative* mechanisms might be removed. They constitute a very grave difficulty in all theories of evolution. Various evidence, mostly ambiguous but as a whole significant, does suggest that in special cases, by violent treatments, the germ-cells of animals may be affected, more or less injuriously, and that the consequences may persist at least for some generations; but that does not help us with the problem of adaptation. Dr. Kammerer's admission would relegate the Alytes pads to that class of phenomena. Had this been all that was claimed, I should have felt some interest in the matter, but less.

The significance of the story is now reduced. In 1909 we were told that nuptial callosities appeared on the *thumbs* of treated males, and that all the males of the "F_4" generation had them. The claim that this was a true adaptation was made without any qualification whatever. This led to my request (made privately in 1910, published in 1913) that a specimen should be produced. In 1919 we hear for the first time that the swellings appear in various other regions of the arms. When at length a specimen is produced, I find it mounted to display a dark thickening on the palm of the hand, a place which, unless I am mistaken, had not previously been specified. That this was the structure to which Dr. Kammerer particularly wished to direct our attention appears also from the fact that the new photograph sent to Prof. MacBride, which I have not had the privilege of inspecting, was made from it. So far as I am aware, this is the only specimen ever exhibited publicly.

Dr. Kammerer complains that I did not at the Linnean meeting produce "a single one of the many objections" alleged in my letter of June 2. His memory is at fault. My chief objection was the position of the pad on the palm. Any one who attended the meeting will know that I directed very prominent attention to this feature. To make my objection clear and conspicuous I asked in German: "*Das Männchen umarmt sein Weibchen—so*—[turning the backs of my hands inwards]—*nicht?*" To which Dr. Kammerer as I thought nodded assent. No one can have forgotten that the next speaker took me to task for this, saying by a slip, induced I suppose by what he had seen of the specimen, that "of course" the common toad clasps the female with the palms towards her.

Why Dr. Kammerer should think that in writing of his diagrams I had in mind a book of Plate's (which I hear of for the first time), I cannot imagine; for I added the exact references to his own paper of 1909, Figs. 26 and 26*a*. The pictures which I threw on the screen, illustrating the fantastic story of Mendelian segregation in respect of the modified habits, will also be found in his paper 12 *Flugschr. d. Deut. Ges. f. Zuchtungskunde*, 1910, and again in *Natur*, Munich, December 12, 1909, papers to which all readers desiring to see the prodigious scope of the original claims should refer. A more detailed though unillustrated account appears in *Mendel Festschr.*, Brünn, 1911.

I do not propose to rebut the minor allegations made by Dr. Kammerer. Several of these would not have been made had he seen my letter in NATURE of July 3, 1919. The answers to the rest will be evident to those who have followed the discussion.

The question remains, what is the real nature of the swellings in the animal exhibited? That on the palm did not look like a nuptial pad. What there may have been on the back of the hand I do not know. I made no statement about it, though Dr. Kammerer says I did. I might no doubt have asked to see the back, but I had no reason to suppose there was anything more to see. The palmar mark was what we were shown for our conviction. This looked so unlike what I remembered of real *Brunftschwielen* that I did ask in the discussion, "*Wie wissen Sie, dass sie Brunftschwielen sind?*" I knew our frog and toad very well, and, of course, Lataste's drawings of sections, but it was some years since I had looked at other species. I thought that perhaps, where the development is slight, as in *Rana agilis*, the external appearances might be less unlike what I had seen in the Alytes, but they are not. When with that specimen fresh in mind I examined a series of nuptial pads in various Batrachia I realised still more vividly how widely the structure in the Alytes differed from the real thing. In my letter, therefore, I laid stress on the dissimilarity.

Dr. Kammerer writes that his specimen was examined out of the glass by Sir Sidney Harmer and Mr. E. G. Boulenger, but we are not told whether they are among the "dozens" now convinced. Mr. Perkins states that "the epidermal spines are very obvious in the intact specimen." He is the only independent witness, of those whose opinions have reached me, who claims to have seen anything so definite.

I have a strong curiosity to see this Alytes again. Dr. Kammerer challenges me to supply him with apparatus for the purpose of photographing it. I will make a different offer. For the opportunity of examining it at leisure in the British Museum, where comparative series are available, or if preferred in Prof. MacBride's laboratory, I am willing to pay 25*l*. either to the Versuchsanstalt or to other appropriate authority. Plenty of responsible people travel between Vienna and London, and there should be no difficulty in arranging for safe conveyance.

A Possible Origin of the Nebular Lines.

THE hypothesis that the lines of unknown origin in the spectra of nebulæ are due to the atom of some hitherto undiscovered element ("nebulium") is not the only one that may be advanced. The recently developed quantum theory of band spectra makes it at least possible that these lines could have their origin in a *molecule* with small moment of inertia composed of atoms of those elements which are known to exist in nebulæ. It is proposed in this letter to show that the existing astronomical evidence is not in contradiction to this alternative hypothesis, and also to indulge in some speculation as to the nature of such a molecule.

The Nebular Spectrum.—The absence of band heads in the nebular spectrum does not necessarily preclude the possibility of a molecular origin. In a band spectrum the individual lines of a single band may be arranged in a Deslandres formula,

$$\nu = A \pm 2Bm + Cm^2,$$

where m takes the successive values 1, 2, 3, etc., and the line corresponding to $m=0$ is missing. The lines, therefore, arrange themselves in a positive (R) and negative (S) branch on either side of the missing line $m=0$; the band head is due to the overlaying of one or other branch on itself, depending upon the sign of C, and occurs in general only for large values of m. To a first approximation, however, the lines in either branch are equally spaced with a separation equal to 2B, where on the quantum theory of band spectra (Sommerfeld, "Atombau," chap. 7) B is inversely proportional to the moment of inertia of the molecule. The smaller this moment of inertia the more widely spaced will be the lines, and from the Boltzmann probability factor the fewer there will be of them. Accordingly, if the hypothetical molecular carrier of the nebular spectrum has a small moment of inertia, the resultant spectrum will consist of isolated lines with no band heads—in general agreement with that observed.

Slightly more positive evidence can be gained from a closer consideration of the nebular spectrum. The important work of Wright (Lick Observatory Publications, vol. 13) has shown that the nebulæ may be arranged in a series from low excitation (strong H, no He lines) through medium to high excitation (H and strong He$^+$ lines). At the top of the accompanying diagram (Fig. 1) are shown the positions (on a wave number scale) and intensities, as given by Wright, of the nebular lines of unknown origin for B.D. +30° 3639 (low excitation) and N.G.C. 7027 (high excitation). For convenience of reference the high excitation spectrum is also repeated at the bottom of the diagram; the dotted lines shown in this spectrum are suspected nebular lines which occur in nebulæ of medium excitation, but not in N.G.C. 7027.

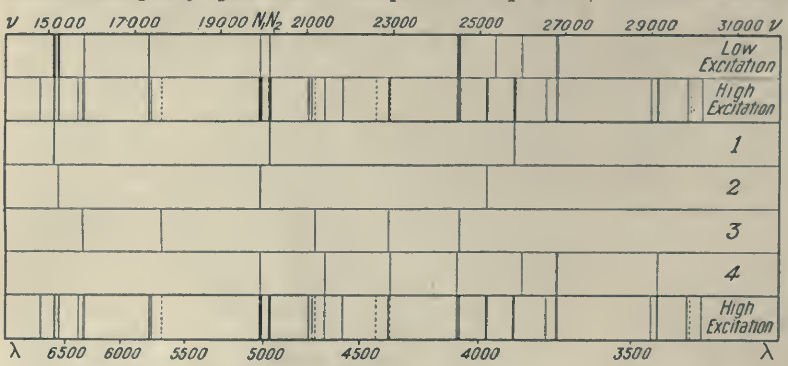

FIG. 1.

The change in intensity and in the number of the nebular lines with increase in excitation is very striking, and this fact may be used in an attempt to select band lines in the spectrum. For the intensity of a line depends primarily on the number of molecules which are in the particular quantum state m, and, according to the Maxwellian distribution of rotational velocities, with increase in excitation the maximum of rotational speeds will shift to the higher quantum numbers. Thus, for low excitation, lines corresponding to $m=\pm 1$ will be strong, but with increase in excitation the lines $m=\pm 2$, ± 3 will gain at the expense of $m=\pm 1$. Using this as a guide, a number of possible band groupings have been suspected in the nebular spectrum, and these are shown as Nos. 1, 2, 3, 4, in Fig. 1. A few words of comment may be made on these.

Nos. 1, 2.—These two groupings comprise the six strongest lines in the spectrum, including N_1, N_2, 3967, 3868. It will be noted how the maximum of intensity shifts from the red lines to the violet with increase in excitation. It has been assumed that each grouping is a positive (R) branch of a single band, and the constants of the Deslandres formula have been computed.

$$\text{(No. 1)}\quad \nu = 10915{\cdot}9 + 3916{\cdot}3m + 352{\cdot}9m^2,$$
$$\text{(No. 2)}\quad \nu = 11098{\cdot}4 + 3903{\cdot}6m + 265{\cdot}4m^2.$$

The close similarity of the constants B for each group suggests that 1 and 2 are two positive branches of a single band with zero line far out in the infra red. Curtis has found in the He_2 spectrum (Proc. Roy. Soc. A, 101, 38, 1922), a band (λ5730) with two positive branches with slightly different (12 wave numbers) values for the zero lines.

No. 3.—This suspected band contains four lines with a dubious fifth, and consists of a positive (R) and negative (S) branch with the line $m=0$ as usual missing. Using the lines with wave numbers S (1) 17679, R (1) 21219·2 and R (2) 22912·50 to compute constants, the following formula is reached:

$$\nu = 19474{\cdot}7 \pm 1770{\cdot}1m - 25{\cdot}6m^2.$$

The computed wave number of S (2) is 15832, and there is an observed line at 15836 (±3), which may be considered satisfactory agreement. The computed wave length of R (3) is 24555, and there is a strong line at 24571·5 (±0·1). The agreement is not satisfactory, the intensity relations are not satisfactory, and it is accordingly very doubtful whether this line belongs to the group. The remaining four, however, make a satisfactory group, and it will be noted that while the lines R(1), S(1) make their appearance in nebulæ of medium excitation, the intensity is transferred to R(2), S(2) in the nebula of high excitation.

No. 4.—This suspected band contains eight lines, which may be divided into a negative (S), a positive (R), and a zero (Q) branch. The designations, wave lengths, and wave numbers are given in the accompanying table. The lines marked with asterisks were used in computing the constants for the R and S branches, namely,

$$\nu = 27586{\cdot}1 \pm 1560{\cdot}6m + 7{\cdot}4m^2;$$

from this was computed in the usual way the formula for the Q branch, namely,

$$\nu = 26805{\cdot}8 + 7{\cdot}4m^2.$$

The agreement between the observed and computed values can be seen from the table below. It is sufficiently close to suggest, in view of the approximate character of the band formula used, that there may be some reality in this grouping. As usual the intensity is transferred from the lines with low quantum numbers to those with high increase in excitation. It will be noted that the line N_1 is used in this grouping as well as in No. 2, and the suggestion is that this line is a close double of a strong and weak component, the latter of which belongs to the present group.

Designation.	Wave Length.	Wave No. (comp.).	Wave No. (obs.).	
S(5)	5006·84	19967·13*	19967·13	±0·04
S(4)	4658·2	21461·5*	21461·5	0·5
S(3)	4353	22964·6	22966	5·0
S(2)	4076·2	24494·4	24525·61	0·1
S(1)	3840·2	26032·9*	26032·9	0·7
Q(1)	3728·91	26813·2	26809·87	0·2
Q(2)	3726·16	26835·3	26829·65	0·3
R(1)	3426·2	29154·1	29178·5	±2·0

To summarise, of 34 lines in the nebular spectrum, 17, including the strongest, have been arranged in suspected band groups. Without additional evidence, however, no conclusion can be safely drawn as to the reality of these groups. While the numerical agreements are not unsatisfactory, it is far from impossible that such coincidences are fortuitous. Confirmation would be lent to this scheme if new lines could be found which would fall into one or other of the above bands; exposures of nebular spectra have been made here of as long as twenty hours without, however, detecting any new lines. In the meantime, then, until further evidence is forthcoming, the reality of the above groups must remain in doubt, and the only conclusion that may be safely drawn is that there is no inherent difficulty in supposing the nebular spectrum to have its origin in a molecular carrier.

Nature of the Hypothetical Molecule.—As the general appearance of the spectrum and the separation of the suspected band lines suggest, the moment of inertia of the hypothetical molecule must be small (of the order of 2×10^{-42} gm. cm.^{2}). So small a moment of inertia clearly suggests that the atoms which constitute the molecule must be of small mass. Of the elements hydrogen, helium, carbon, and nitrogen known to exist in nebulæ, only atoms of the first two are, therefore, likely to form the hypothetical molecule. The spectra of the H_2 and He_2 molecules are already known, and there is no similarity between either of these spectra on one hand and the nebular spectrum on the other. As a working hypothesis the suggestion may therefore be made that the nebular spectrum has its origin in a H He molecule with a moment of inertia of the order of 2×10^{-42} gm. cm.^{2}, and a resultant separation of the H and He nuclei of about $0{\cdot}1 \times 10^{-8}$ cm. In view of the known chemical activity of atomic hydrogen and also of the existence of molecular helium, it is not improbable that such molecules must occasionally be formed. In fact, Aston ("Isotopes," p. 99) has suspected their existence in his positive ray experiments.

Probably the chief merit in the foregoing discussion is that it furnishes a suggestive working hypothesis for finding the nebular lines in the laboratory. The problem becomes one, not of finding new elements—a difficult matter—but of examining the spectrum of a molecule which is known to exist. While our knowledge of physical conditions in the nebulæ is still obscure, yet it may serve as a guide to experimental investigation. Clearly atomic hydrogen and helium must be present in a highly rarefied condition and presumably at low temperatures; such a condition can be duplicated probably by the introduction of some helium in the centre of a long Wood vacuum tube where atomic hydrogen is known to exist in abundant quantities. Not only must the conditions be right for the formation of the molecule, but once formed it must be excited to radiation; for a nebular absorption spectrum is not known to exist, and hence the normal hypothetical molecule must radiate in the far ultra-violet. Such difficult problems of laboratory technique must be left to others; an attempt, however, will be made here to secure further astronomical evidence on the reality or otherwise of the suspected bands.

H. H. PLASKETT.

Dominion Astrophysical Observatory,
Victoria, August 4.

Dutch Pendulum Observations in Submarines.

THREE submarines of the Dutch Royal Navy with the mother-ship *Pelikaan* are about to sail for Java. At the request of the Dutch Geodetical Committee (Rijkscommissie voor Graadmeting en Waterpassing), his Excellency the Minister of Marine has allowed Dr. F. A. Vening Meinesz, engineer appointed to the Committee, to join one of the submarines for the purpose of making pendulum observations on board during the voyage.

For several years Dr. Vening Meinesz has been engaged in determining the intensity of gravity at 51 stations in the Netherlands. The difficulties caused by the extreme mobility of the soil in part of the country induced him to work out a method for the elimination of the resulting disturbances; this has been applied with complete success, as will be shown in a publication—in French—to appear shortly. It was hoped that the extended theory might be applied to pendulum observations on board an ocean steamer. A first trial, however, on a steamer of the Koninklijke Paketvaart Maatschappij from Ymuiden to Flushing failed through the very turbulent sea.

In the spring of this year, Dr. Vening Meinesz gave a short exposition of his theory at the Physical and Medical Congress at Maastricht. Prof. F. K. Th. van Itterson, director of the Government mines at Heerlen, suggested that the observations might be successfully carried out on board a submerged submarine, where the disturbances could be expected to be less than on the surface of the sea. His opinion was found to be correct at a trial on board a submarine at the Helder. Notwithstanding the fact that a heavy gale was blowing and the sea was very rough, the movements of the ship, submerged at a depth of 15 metres, were so trifling that the amplitude of the pendulums, which were hanging quietly at first, amounted to no more than 8′-12′ after a quarter of an hour.

A brief exposition of the theory as given by Dr. Vening Meinesz at the Congress at Maastricht and published in *de Ingenieur*, 1923, No. 18, may be of interest.

The influence of the horizontal and vertical movements of the ship may be eliminated by the use of two pairs of pendulums swinging together from the same support, the two pairs moving in two planes. In the Von Sterneck apparatus used by Dr. Vening Meinesz, these two planes are at right angles to each other. The movements of each pendulum are to be photographically recorded.

The equation of movement of a pendulum is

$$\frac{g}{l}\theta+\theta''+\mathrm{D}=0,$$

θ being the angle of inclination and l the length of the pendulum, D a term introduced by the disturbances.

Putting $$\frac{g}{l}=n^2$$

and introducing the complex variable

$$q=\theta-\frac{i}{n}\theta',$$

which may be represented by a vector, the projection of which on the real axis is the angle of inclination θ, the equation assumes the form

$$q'=inq+i\frac{\mathrm{D}}{n},$$

and after integration

$$q=(q_0+\Delta^t q)e^{int}, \quad . \quad . \quad . \quad . \quad (1)$$

where $$\Delta^t q=\frac{i}{n}\int_0^t \mathrm{D}e^{-int}dt.$$

If $\mathrm{D}=0$, the constant vector q_0 is rotating with a constant velocity n.

If $\mathrm{D}\neq 0$, q varies by the quantity $\Delta^t q$ in the time t. The change which the term D causes in the amplitude, *i.e.* the length $q_0+\Delta^t q$, and in the period of the oscillation, *i.e.* the time in which $q_0+\Delta^t q$ describes the angle π, may be readily inferred from Fig. 1.

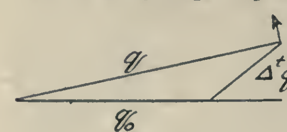

FIG. 1.

Equation (1) enables us to investigate the influence of the different causes of disturbance.

(1) *Horizontal Movements.*—If the acceleration of the horizontal movement is y'', we have $\mathrm{D}=y''/l$; using two pendulums with equal values for n and y'' and swinging in the same plane, the value of $\Delta^t q$ is the same for both; hence the difference of the oscillation vectors is constant. This constant vector may thus be considered as the oscillation vector of an undisturbed pendulum having the same period of oscillation. The angle of inclination of this hypothetical pendulum is equal to the difference between the angles of inclination of the two real pendulums.

Each pair of pendulums of the apparatus may thus be substituted by a hypothetical pendulum free from the disturbances caused by horizontal movements.

(2) *Vertical Movements.*—The influence of the vertical movements is less than that of the horizontal. On the other hand, it is impossible to eliminate it entirely. Since the vertical acceleration is indissolubly connected with the acceleration of gravity, it is obvious that elimination of the former would imply elimination of the latter.

From the following reasoning it appears, however, that we are able to eliminate the influence which depends on the phase of the pendulum, so that the result is only affected by the mean vertical acceleration. Expressing the vertical acceleration by y'', then we have $\mathrm{D}=(x''/l)\theta$. If we divide the equation of movement by q:

$$\frac{q'}{q}=in+\frac{in}{g}x''\frac{\theta}{q},$$

and represent the phase of the pendulum by ϕ,

$$\theta=a\cos\phi \text{ and } q=ae^{i\phi},$$

where a is the amplitude; thus

$$\frac{\theta}{q}=\tfrac{1}{2}+\tfrac{1}{2}e^{-2i\phi},$$

the equation may be written:

$$\frac{q'}{q}=in+\frac{in}{2g}x''+\frac{in}{2g}x''e^{-2i\phi}.$$

Each hypothetical pendulum corresponding with a pair of pendulums of the apparatus gives a similar equation; the two may be distinguished one from the other by the suffixes 1 and 2. The following relation is easily derived:

$$in+\frac{in}{2g}x''=\frac{(q_1'/q')-(q_2'/q_2)e^{2i(\phi_2-\phi_1)}}{1-e^{2i(\phi_2-\phi_1)}}.$$

Passing to real quantities and putting the ratio of the amplitudes $a_2/a_1=p$, we get

$$n+\frac{n}{2g}x''=\frac{\phi_1'+\phi_2'}{2}-\tfrac{1}{2}\frac{p'}{p}\cot(\phi_2-\phi_1).$$

For the right-hand member of this equation the observations yield a mean value; the first term is the mean velocity of the phase.

For the computation of n it is necessary to know the mean value of x'' during the time between the observations; obviously we may take for this value

$$\frac{1}{t}(x'_{\text{end}}-x'_{\text{beginning}}).$$

If the beginning and the end of the observations coincide with the moments when the vertical velocity of the support may be supposed to be 0, the same is true for the mean value of x''. These moments cannot be accurately ascertained, but we may take the moments when the vertical movement changes its direction. The resulting error can be reduced *ad libitum* by extending the duration of the observations.

In this way the horizontal as well as the vertical movements of the support may be eliminated. The influence of the inclination of the support can also be taken into account. In order to obtain the required accuracy, however, it should not be allowed to exceed 1° in either direction.

J. J. A. MULLER,

Zeist, August 18.

Long-range Particles from Radium-active Deposit.

WHILE studying the H-particles found by Sir Ernest Rutherford to be the first disintegration product of aluminium and some other atoms, under α-bombardment, we have developed a new method for obtaining strong and practically constant sources of such radiation. The method consists in enclosing dry radium emanation mixed with pure oxygen within thin-walled capillaries of hard (potassium) glass, lined with some $12\,\mu$ thickness of aluminium foil pressing well against the glass. As a small number of long-range particles were given off from the glass itself, we have also made use of capillaries drawn out from tubes of pure silica.

Some of the elements not previously investigated for H-particles have been examined in this manner by the scintillation method, the results proving that scandium, vanadium, cobalt, arsenic, and indium—the three first as oxides, the last two as metallic mirror and as chloride respectively—do not give off long-range particles (>30 cm. of air) to a greater number than 3 or 4 times $\mathrm{N}.10^{-8}$, where N is the number of α-particles from radium C discharged

per second within the capillary. A very small number of such particles were actually observed with most of these substances, the scintillations being, however, too few for anything definite to be said at present regarding their origin.

Having regarded quartz as an ideal non-active substance to be used in these experiments, we were somewhat disappointed at finding, with a more thin-walled capillary than the others, a relatively large number of faint but distinct scintillations from the unlined part of the quartz, the rest of the capillary, lined with a thin coating of scandium oxide, giving no such scintillations. These scintillations practically disappeared when the total absorption was raised from 10 to 15 cm. by interposition of a mica filter. Similar results were afterwards obtained with other thin-walled capillaries; the absorption curve for the H-particles is being at present more accurately determined in this Institute.

Considering the high purity of the quartz, and the care taken to free the emanation from moisture and other hydrogen contaminations, we see no other way to explain this observation than by assuming silicon to give off H-particles of the maximal range just stated.

We have recently constructed a different emanation vessel in which the substances to be examined are spread in thin layers over copper foil of about 4 cm. absorbing power, forming the bottom of a narrow emanation trough, the emergent H-particles being counted from below with a scintilloscope. In this manner we have obtained fairly conclusive evidence that H-particles are also given off from the following elements :

Silicon, as element, approximate maximal range 18 cm. air.
Beryllium, as oxide, approximate maximal range 12 cm. air.
Magnesium, as oxide, approximate maximal range 13 cm. air.
Lithium, as carbonate, approximate maximal range 10 cm. air.

With lithium the results are less definite than with the others, mainly owing to the difficulty of excluding contamination with hydrogen compounds.

Blank experiments with only the bare copper foil (which had previously been bombarded with cathode rays in a vacuum to remove occluded gases) showed a much smaller number of H-particles. and, judging from the absorption curve, due to "neutral" H-particles. We are having the apparatus reconstructed so as to eliminate errors from this source.

A more detailed description of our experimental arrangement is being published shortly. The emanation capillaries will be used in this Institute also for studying atomic disintegration by the Wilson method.

Our results seem so far to indicate that the hydrogen nucleus is a more common constituent of the lighter atoms than one has hitherto been inclined to believe.

The Menace to Civilisation: an Appeal to Men of Science.

MAY I ask the hospitality of the columns of NATURE for an appeal to men of science throughout the world ?

The enthusiastic pioneers of Victorian times, whose work underlies the fabric of modern science, always thought of themselves as beneficent agents. In them scientific ardour was joined with devotion to the welfare of humanity. They saw science releasing men from toil, improving their health and comfort, spreading toleration and promoting international understanding. Some part of these hopes has been realised, while others we may yet hope to realise.

But we are now faced with pressing and imminent dangers which the Victorians could not foresee. Science has immensely increased the destructive powers of mankind, without in the least diminishing their readiness to use those powers. It has been stated by a member of the Government that since the Armistice, "in the different civilised countries" no less than five kinds of poison gas have been invented, each more deadly than any used in the War. This sentence is not quoted to illustrate the conception of civilisation current among politicians, but merely to indicate the present tendency of research in one direction to amplify the means of destruction which will be available in the next war. At any moment a caprice of politics, or a vicissitude of international trade, may plunge us into a war which we shall be quite unable to prevent. In that war, which every year's delay will make the more deadly, the most incredible powers of destroying not only human life, but the whole apparatus of our civilisation, will be entrusted to boys of eighteen, and, for all we know, to African negroes. Science will have crushed the civilisation that gave it birth.

If the forces now at work are allowed free play this result may reasonably be regarded as not only a probability, but also a practical certainty ; quite as certain, for example, as was the French Revolution when Lord Chesterfield prophesied its coming. Whether the storm will burst on us or on our grandchildren we cannot tell, but that the heavens are big with it is plain to see. The really desperate part of the position is that, so far as Europe goes, the total collapse of all that we have learnt to know as civilised life is regarded with almost complete indifference. Each nation is on a par with the man in Æsop, whose only care, when the ship was sinking, was to take up such a position that he could have the pleasure of seeing his enemy perish before he succumbed himself. So long as we have an Air Force which can destroy the other people's capital at least as soon as they destroy ours, we are quite happy, so far as Parliament and the Press are concerned, at any rate.

Is it too much to hope for something better from men and women who have had a scientific training, who have learnt in their work the essential fellowship of all servants of science, and whose consciences must tell them that it is their efforts, in whatever spirit they may have been conceived, which are now in danger of being directly responsible for the most appalling disaster in human history ? It is not necessary to speak of the terror-stricken multitudes in the doomed cities, the screams of women and children in helpless anguish, the tragedy of Pompeii repeated on a thousand-fold scale ; nor does it take much imagination to foresee the red ruin and breaking up of laws that will follow : can any one think that a world that has suffered such unimaginable horrors from science will hereafter tolerate it in the hope that it may do something to alleviate cancer ? In destroying civilisation, science will also destroy itself.

The only hope for the world lies in the men of science. It is their paramount duty to see that the knowledge they win is used only for the good of their race and not for its destruction. The day is past when they can simply throw their discoveries out into the world and let them take their chance. In my opinion the only possible salvation lies in the immediate formation of an international league of men and women of science who shall pledge themselves not only to fight against war, but to refuse to

give their assistance in any scientific capacity in the event of war coming despite their efforts to prevent it. Without trained technical assistance the warfare of the future will be impossible. If they wish to carry a rifle, by all means let them: they will not do much harm with a rifle. But a refusal to give their technical assistance would not only bring any war to a standstill, but would also be the strongest possible guarantee against it breaking out. If this measure is not taken, and promptly, we may well fear that the new order that rises from the ruins of the old will persecute science as whole-heartedly as ever did the rulers of the Middle Ages, and with better reason.

The Heisenberg Theory of the Anomalous Zeeman Effect.

IN his theory for doublets Heisenberg (*Zeit. f. Physik*, 8, 273, 1922) assumes that the atom may be looked at as made of two parts: (1) the shell and (2) the valence electron. Expressing angular momenta in multiples of $h/2\pi$ and choosing the direction of the angular momentum of the shell as positive, the electron is allowed to have angular momenta $I=\frac{1}{2}, \pm\frac{3}{2}, \pm\frac{5}{2}, \ldots$ in the $s, p, d, \ldots$ states respectively, and the shell has in all of the states the angular momentum $\frac{1}{2}$. The observed Zeeman patterns show that $I=\frac{3}{2}$ in $2p_1$ and $I=-\frac{3}{2}$ in $2p_2$. The observed energy levels show that the energy in $2p_1$ is higher than in $2p_2$. The writer experienced the following difficulty in accounting for this relative position of energy levels.

Various hypotheses can be made as to the nature of the interaction between the shell and the electron. We may suppose, for example, that the magnetic field of the electron induces a precession in the shell in a manner analogous to that in which an external magnetic field induces a precession in the electronic orbit. We then suppose, too, that the field due to the shell produces a precession of the electron. The contribution to the kinetic energy of each of these precessions is $-\mu H \cos \vartheta$, where μ, H, ϑ are respectively the magnetic moment of the shell, the field at the shell due to the electron, and the angle between the positive directions of μ and H. The contribution of both is $-2\mu H \cos\vartheta$. The mutual energy of the magnetic fields is $+\mu H \cos\vartheta$. There is no contribution to the energy of the electric field because the radius of the orbits is unchanged (Sommerfeld, "Atombau und Spektrallinien," third edition, p. 380). The energy to be added to that coming from other sources is then $-\mu H \cos\vartheta$. On this hypothesis, therefore, the $2p_1$ state has the lower energy, while the reverse is actually the case.

If there were no induced precession in the shell, but if the electronic precession should be still hypothesised, the $2p_1$ and the $2p_2$ levels would coincide.

If the shell and the electron should be supposed to have no induced precession, the energy of the magnetic field becomes the only source for the energy of separation of the $2p_2$ levels. This energy is $+\mu H \cos\vartheta$ and thus makes the $2p_1$ level the state of higher energy, as it is actually observed to be.

It seems questionable, however, whether the hypothesis just made can be maintained, for it presupposes that the dimensions of the orbits of the valence and the shell electrons are the same in the $2p_1$ and the $2p_2$ state. This may be contrary to quantum conditions if the energy of the magnetic field is considered as kinetic energy. If two electrons should be constrained to move on the opposite ends of a diameter of a circle of variable radius (as in Bohr's first helium model), the kinetic energy becomes of the form:

$$\frac{m_1 v_1^2}{2} + \frac{m_2 v_2^2}{2} + M_{12} v_1 v_2 = (m_1 + M_{12}) v_1^2,$$

where m_1, m_2, v_1, v_2 are respectively the masses and velocities of the electrons and $M_{12}v_1v_2$ is the mutual energy of their magnetic fields. The case is formally analogous to the hydrogen atom, and a substitution in well-known formulas shows that the total energy becomes decreased if M_{12} is increased. The reason for this is traceable to a decrease in the radius of the orbit. Thus again the effect on the $2p_1$ level is opposite to that observed.

The matter of the sign of the energy in the doublet terms thus does not appear to the writer to be sufficiently clear.

The same question of sign is present in the case of triplet terms. In addition to this the $2p_2$ term of triplets does not seem to be accounted for properly by Heisenberg. His arrangement of angular momenta accounts for the energy level of the $2p_2$ state. I obtain, however, a different result for the Zeeman resolution. On going through Heisenberg's calculation his lines 5, 6, counted from the bottom of page 292 and leading to the equation $\cos\theta = m/p_{12}$ do not appear obvious. His p_{12} is the projection of a vector in the direction J, m is the projection of the same vector in the direction H, and θ is the angle between J and H. The above equation is then $\cos(JH) = \cos(AH)/\cos(AJ)$, which does not appear to be generally valid. It becomes correct, however, if A and J are the same. They are the same for doublets and for the $2p_1$, $2p_3$ terms of triplets, but not for the $2p_2$ term.

Thunderstorms and Ozone.

THE question—What chemical changes, if any, are associated with atmospheric electrical discharges?—does not appear hitherto to have received a definite answer. Nitrogen peroxide and ozone are both referred to in scientific literature, although neither appears to have been satisfactorily identified, and their presence has been perhaps inferred from the phenomena observed while "sparking" air by artificial means.

No reliance can be placed upon observations made with guaiacum or starch-potassium iodide papers, and the work of the more serious investigators on ozone in the air (Pring, Proc. Roy. Soc., 1914, 90a, 204; Hayhurst and Pring, Jour. Chem. Soc., 1910, 868; Kaiser and McMaster, *Am. Chem.*, July 1, 1908, 39, 96; Henriet and Bonissy, *Comp. rend.*, 1908, 146, 977; and the older work of Houzeau, Schöne, H. de Varigny, Hached and Arny, and Thierry) has thrown no light on this subject.

Unexpectedly clear evidence on the above point was obtained by me in connexion with the severe thunderstorm which passed over the metropolis from south to north, during the early hours of July 10 last. The lightning on this occasion was generally described in the London press as the most vivid and prolonged display in living memory (*vide* NATURE, July 21, p. 113).

I have for some time been measuring the proportion of certain variable gaseous constituents in London and country air, and succeeded last spring in working out an improved method of estimating ozone, in

which inaccuracies in the potassium iodide method of estimation, namely, the interference of sulphur dioxide and serious loss of iodine by volatilisation, were overcome by first removing the former, and then allowing the ozonised air to react on potassium iodide in the presence of a known volume of N/100 thiosulphate solution, which fixes the liberated iodine. The apparatus used will be described later, together with the general results.

The measurements form two series, determinations of the sulphur dioxide and nitrogen peroxide in dilute sodium bicarbonate, alternating with those of ozone, sulphur dioxide, and ammonia. Each test proceeds for about three days, and is conducted in duplicate at the village of Upminster, Essex (17 miles E.N.E. of Charing Cross), and at Messrs. Jeyes' laboratory, Plaistow, E., 5000-10,000 litres of the outside air in each case being examined. The former estimation was in progress during the storm at both places. Upminster lay on the eastern fringe of the storm track. It experienced severe lightning, but only 0·36 inches of rain fell there, as against 2 inches at the London station, which was nearer the centre. The proportion of nitrogen peroxide before, during, and after the storm (recorded in terms of 1 volume of NO_2 in . . . million volumes of air) was as follows :—

	Before.	During.	Since.
London	1 in 120 millions.	1 in 114 millions.	1 in 134 millions.
Upminster . .	1 in 350 millions.	1 in 440 millions.	1 in 400 millions.

There was, therefore, no appreciable increase in nitrogen peroxide in the air during the storm. The sulphur dioxide and ammonia remained practically constant during the above period, the proportion of the former being—London, 1 in 20 millions, Upminster, 1 in 45 millions, while the ammonia amounted to 1 in 200 millions in both.

This result has been confirmed by an examination of rain water. I have not yet collected during a thunderstorm a specimen of London rain sufficiently free from suspended particles (which completely mask its analysis) to be trustworthy; but in a bright sample collected during a thunderstorm at Upminster, the nitric acid content proved to be equivalent to a N/200,000 nitric acid solution, which is slightly under the average of several samples collected during still conditions.

The proportion of ozone present a few days before the storm was 1 in 23 millions in London, and 1 in 22 millions at Upminster, but the average amount present between July 13 and 16 was 1 in 3·2 millions in London, and 1 in 14·8 millions in the country. *There was, therefore, more than seven times the previous quantity of ozone present in London air three to six days after the storm,* and the proportion must have been appreciably higher than this at the time, owing to the subsequent loss by diffusion and convection, and to the change into oxygen, which can be readily proved to occur. A fortnight later the proportion of ozone at both places was 1 in 18·5 millions.

Confirmation of the above results has been obtained during a much less spectacular thunderstorm, which visited both stations about midday on August 24 last. A few days previously the proportion of ozone found was—London, 1 in 22·7 millions, Upminster, 1 in 18·8 millions. Measurements of the ozone had been in progress nearly twenty-four hours when the storm occurred, and were continued for the next three days. The average content for the four days was—London, 1 in 9·71 millions, Upminster, 1 in 7·8 millions, *the proportion of ozone having thus been more than doubled in each instance.*

I hope to devise a portable modification of the apparatus that will enable estimations to be completed in two or three hours, in which case much more detailed information on the subject will be obtained than is possible in three- to four-day averages.

WILLIAM C. REYNOLDS.

"Wharfedale," Upminster, Essex,

A Method for Demonstrating the Stages in the Life History of Monocystis in Practical Class Work.

IN the text-books on practical zoology in common use in zoological laboratories, the method advocated for making preparations of the contents of the vesiculæ seminales of the earthworm for the examination of the stages in the life history of Monocystis is what is usually known as the cover-glass method (*vide* Marshall and Hurst, "Practical Zoology," 9th edition, p. 13). It is, I believe, a matter of common experience that, when this method is adopted, only a small percentage of the students succeed in finding in their own preparations all, or even the majority, of the important stages. Generally only the trophozoite and sporocyst stages are found, and demonstration specimens have to be resorted to to fill in the gaps.

This repeated failure in previous years suggested the trial of a modification of the method, and the result may be of interest to those who have charge of practical classes. The preliminaries are the same. The vesiculæ seminales (preferably the posterior lateral vesiculæ seminales, as these appear to contain more specimens) are removed from a freshly killed (with chloroform) worm, and placed in a watch-glass with about five to six times their bulk of normal salt solution. The material is teased thoroughly with needles. A drop of the fluid and particularly a portion of the teased wall of the vesicula seminalis is placed on a slide and, if desired, faintly stained with Dahlia. Cover with a cover-glass, and the preparation is ready for examination. If the operation has been rapid and the staining only slight, the trophozoites will be found to be still alive and exhibiting the characteristic gregarine movement. The encysted stages will be found embedded in the tissue of the wall of the vesicula seminalis, and it is for this reason that stress should be laid upon the inclusion of a portion of the wall in the preparation. In this situation the stages which are not usually found, *i.e.* the gametocytes in association, and more rarely gametocytes showing fragmentation into gametes, occur, as well as large numbers of sporocysts containing spores.

Below is a summary of the results (as recorded by the students themselves) obtained with a class of twenty students, one worm serving for every two students. The class was held in May.

Stages.	Percentage of Students obtaining Stages.
Trophozoite	85
Gametocytes in association . .	60
Gametocytes showing fragmentation into gametes	25
Sporocysts with spores . . .	95

As experience shows, worms vary considerably in the extent to which they are infested with Monocystis, but the above result may be taken as representative.

It may be of interest also to record that the worms used by the class had been kept in the laboratory from the previous November. The method adopted was to keep them in a tank in a compost made up of one third earth and two-thirds moist leaf-mould. The compost must be kept reasonably moist, and it was found advantageous to change it about every three weeks.

The British Association at Liverpool.

Sir Ernest Rutherford, F.R.S.

The ninety-first annual meeting of the British Association for the Advancement of Science opened on Wednesday evening with a brilliant address by the president, Sir Ernest Rutherford, on the electrical structure of matter—a subject to which he has made many notable contributions and on which he is a leading exponent. He is, we believe, the youngest president appointed by the Council since the foundation of the Association in 1831. The average age of the presidents of the Association is nearly sixty-two years; and until this year the youngest presidents were Sir Arthur Rucker, Sir Joseph Thomson, and Dr. Bateson, each of whom was fifty-three years of age when holding the office.

Sir Ernest Rutherford was born at Nelson, New Zealand, on August 30, 1871, and, after graduating in the University of New Zealand, proceeded with an 1851 Exhibition Science Scholarship to Trinity College, Cambridge, where he at once took up research at the Cavendish Laboratory, leading in 1897 to a research degree and the Coutts-Trotter Scholarship. In the following year, and on the advice of Sir Joseph Thomson, he was appointed Macdonald professor of physics in McGill University, Montreal, where he remained until 1907 and continued with such remarkable success the studies of the properties of radioactive substances in which he had shown great originality and insight at Cambridge. It was while he was at Montreal that Sir Ernest Rutherford was joined by Prof. Soddy from Oxford, and together they proved by experimental evidence that radioactivity is an atomic phenomenon accompanied by chemical changes in which new types of matter are produced, that the changes must occur within the atom, and that the radioactive substances must be undergoing transformation. It was twenty-one years ago when this theory of the cause and nature of radioactivity was published in the *Philosophical Magazine*, and the advances in atomic physics and chemistry since then have been both startling and stimulating. The distinguishing characteristic of Sir Ernest Rutherford's work has always been extreme care in verifying every step by thorough experimental test, and it is on this account that a theory which at first provoked much adverse criticism has become an established scientific principle.

[*Photo: Russell and Sons, London.*

The work done by Sir Ernest Rutherford at Montreal, though so novel and suggestive, represented only the first harvest in a field which has been growing in extent and increasing in fertility ever since. While Langworthy professor of physics in the University of Manchester from 1907 to 1919, and as Cavendish professor of physics in the University of Cambridge during the past four years, he and his pupils have cultivated this field with astonishing success. Attention has been given particularly to the α-particle, which is liberated spontaneously in radioactive transformations and has proved of special service in elucidating the structure of the atom. Bombardment of the lighter elements, particularly of nitrogen and aluminium, by these swift projectiles, has disclosed the presence of hydrogen nuclei within the nuclei of some of these elements, and this work has played an important part in modern theories of the structure of matter, with which Sir Ernest Rutherford deals in his presidential address, reproduced in this week's Supplement to Nature.

Arrangements for the Meeting.

The meeting of the British Association now being held in Liverpool is of particular importance, both by reason of the large attendance and through the weighty scientific matters under discussion. In other respects also it is noteworthy, on account of departure from what are traditional habits of the Association.

The president's address in the Philharmonic Hall was not a mere reading of written matter. The

printed address was available as usual, but was given as a discourse illustrated by lantern slides and models. The address was broadcasted, and was reproduced in another hall in the city at an overflow meeting: being thus communicated to a wider audience than has ever previously been the case. No better example of the advancement of science in the Association could be made.

The Sectional programmes are extraordinarily full and exhibit an increasing tendency towards afternoon lectures as well as more numerous meetings on the last morning, September 19. At the same time the great increase in both general and sectional excursions and visits to works is loading the programme to an extent which must satisfy even the most thirsty for scientific knowledge. The Local Committee has spared no trouble to make these excursions and visits to works a success. There are about fifty-five of them, and a brief account of what visitors can see in each is contained in a dainty excursion guide, a copy of which is given to each member. Apart from its utility at the moment, this little book forms a useful companion volume to the handbook "Merseyside."

The scientific exhibition at the Central Technical School, and the soiree at the University, represent together a great development of the small sectional and other exhibits which have been a feature of many meetings. They attempt to show all that is latest in science, in apparatus, experiment, etc., and at the same time, through lecturettes and cinema exhibitions, to present much new matter in a form of more general interest than papers in the Sections addressed to specialists only. While the latter arouse the interest of the philosopher, the former seek to promote general interest in science and its application. The organisation of this exhibition and soiree has represented an enormous amount of work.

It had originally been decided to have no arrangements for the evening of Monday, September 17, but it was felt that many visiting members would like some recreation, so the Local Committee has taken several hundred seats at the Playhouse, when the Liverpool Repertory Theatre Co. will present two plays. Application for tickets, which will be free, must be made in the Reception Room, and seats will be allocated in order of application.

On Sunday morning, September 16, special services will be held in many places of worship, and Canon Barnes will preach and the Lord Mayor attend in state the service at the Lady Chapel of the Liverpool Cathedral. In the afternoon of the same day there will be an organ recital in the Great Hall at St. George's Hall.

An outstanding feature of the meeting is the number of foreign and colonial visitors. Representative men of science from Norway, Sweden, Denmark, Holland, Switzerland, France, Italy, Hungary, United States and Canada are present, as well as a representative from India.

This reunion of scientific workers from so many parts of the globe cannot but be to the advantage of science as a whole, and indirectly help the international nature of science. There seems something peculiarly suitable that such a notable gathering should be held in Liverpool, our most cosmopolitan city and port.

Probably for the first time in its history the housing question has directly touched the Association. The question of accommodation has been a very difficult one for the Local Committee, as at the present time there are practically no vacant rooms even in so large a city. Fortunately Southport, which is quite near, and has an excellent train service to Liverpool, possesses several excellent hotels, and weekly railway tickets at reduced fares are available.

Though most of the Sectional meetings are being held in the University Buildings, Sections E, F, and H meet in the city in the near neighbourhood of the Reception Room. For the general convenience of members, lunch is provided in the Students' Union and in a marquee at the University, and also in St. George's Hall alongside and opening out of the Reception Room.

Through the kindness of the Tramways Committee of the Corporation members are allowed to travel free on tramcars on showing their Association badge.

The members attending the meeting are thus enjoying a busy and profitable week. ALFRED HOLT.

The Japanese Earthquake of September 1.

By DR. CHARLES DAVISON.

SINCE November 4, 1854, the Empire of Japan has experienced no earthquake, not even in 1891, that can be compared in strength and destructiveness with that which occurred about noon on September 1. Semi-destructive shocks, or shocks capable of throwing down chimneys and stone-lamps, are not uncommon in the district round Tokyo and Yokohama, the most notable during recent years being those of February 22, 1880, June 20, 1894, December 8, 1921, and April 26, 1922. The first of these shocks is of interest as it led to an event in the history of seismology, the foundation by Prof. Milne of the Seismological Society of Japan. But the continued existence of the capital and seaport points to their long-standing immunity from destructive earthquakes, though, as they lie close to a well-known seismic zone, it may be for that very reason that this last great movement occurred in their immediate neighbourhood.

How great the disaster is we do not yet know. As usual in an earthquake of this magnitude, railway-lines are crumpled, telegraphs and telephones are destroyed, and our chief news comes, for the first time on such an occasion, by wireless. It is uncertain, too, how much of the destruction was due directly to the earthquake, how much to the fires that broke out immediately and spread at first unchecked owing to the derangement of the water-mains, and how much to the sea-waves that followed. In Yokohama, the earthquake was mainly responsible, for it left little standing for fires to work upon. In Tokyo, not a house is undamaged, and about two-thirds of the city—including, it is reported, the Imperial University, the Imperial Museum, and the

Ministry of Education—are destroyed. The most serious loss is that of the lofty steel-brick buildings recently erected. It was supposed that they would resist a shock of the utmost violence, and if their destruction was, as is probable, due to the earthquake and not to the fire, it may be necessary to prohibit their erection in the future, and this will greatly restrict the manufacturing power of the country. Estimates of the total loss of life vary widely. Some place it as high as half a million, and in Tokyo inquests have already been held on more than 32,000 bodies. There can be little doubt that the work of a few minutes has been more costly in life and treasure to Japan than a great and long-continued war.

There appear to have been no fore-shocks strong enough to give warning of the first and greatest earthquake. Among the crowd of after-shocks that followed, one was strong enough to be felt at Osaka at 2.25 P.M. on September 1. Mr. J. J. Shaw at West Bromwich recorded a second earthquake at 9 A.M. on the same day (6 P.M. Japanese time). On September 2, almost exactly twenty-four hours after the principal shock, seismographs in Great Britain revealed the occurrence of another earthquake, almost as powerful as the first, with an origin at about the same distance and in nearly the same direction as the first. No mention is made of this earthquake in the Japanese reports, unless it is the shock which on the morning of September 2 is said to have destroyed 6000 houses in the town of Kawaguchi. But its origin may have been situated more to the south and possibly near the Bonin Islands.

The number of after-shocks was unusually great. According to the Tokyo Central Observatory, 1039 were recorded between noon on September 1 and 6 A.M. on September 6, the numbers being 356 on September 1 and 2, 289 on September 3, 173 on September 4, 148 on September 5, and 63 during the first quarter of September 6, the usual decline in frequency being thus manifest. In the two months following the great earthquake of 1854, the number of after-shocks actually felt was 443. During the five days after the Mino-Owari earthquake of 1891, 808 shocks were recorded at Gifu. The number of after-shocks, however, seems to depend on the magnitude of the vertical, rather than of the horizontal, displacement; and thus, the large number following the recent earthquake may imply that the movement which caused it possessed a noticeable vertical component.

Other evidence of vertical displacement at the epicentre is provided by the arrival of the sea-waves soon after the earthquake. Little is known about these waves. They appear to have swamped the reclaimed portions of Yokohama and Tokyo and to have caused much damage along the numerous creeks and canals. Many villages along the coast of the peninsula south of Yokohama were washed away. The naval base at Yokosuka (about 10 miles south of Yokohama) was destroyed, partly by the earthquake, partly by the sea-waves. There is no evidence, however, that the waves were of great height like those of the Sanriku earthquake of 1896. And it is important to notice that, of the three cables leading to Tokyo, only one was fractured by the earthquake, the others continuing to work normally.

With regard to the position of the epicentre, we have some, though not much, evidence. The earthquake was evidently stronger at Yokohama than at Tokyo, 16 miles farther north. The sea-waves may have been caused by submarine landslips, but they were probably due to a vertical displacement of the ocean-bed. That the movement at the surface, at any rate in Tokyo Bay, was not very considerable seems to be indicated by the preservation of two of the three lines of cable. The apparent lowness of the sea-waves may have been due to the smallness of the vertical movements, but it may have resulted from a restricted area of submarine displacement, such as would be provided by an epicentral area crossing land on one or both sides of Sagami Bay, the inlet leading up to Tokyo Bay. Not much trust can be placed on the reported disappearance of the island of Oshima, which seems to be near the epicentral district, but it may have taken part in a general movement of subsidence and thus be of diminished area.

For our knowledge of the earthquakes of the Tokyo district, we are chiefly indebted to the labours of Prof. Omori. In two recent numbers of *Seismological Notes* (No. 2, 1922, pp. 1-21, and No. 3, 1922, pp. 1-30) he has described the semi-destructive earthquakes of December 8, 1921, and April 26, 1922, and the distribution of earthquake-origins in the neighbourhood of Tokyo. A glance at the map of Japan will show that the inlet consisting of Sagami Bay and Tokyo Bay runs in a northerly direction up to Tokyo, the entrance to the latter bay being known as the Uraga channel. On the west side, the inlet is bounded by the Sagami-Izu peninsula, and on the east side, by the Awa-Kazusa peninsula. During the eight years 1914–1921, 199 earthquakes originated in the country round Tokyo, and, with few exceptions, in four seismic zones, one off the east coast of the Main Island, the second in the neighbourhood of Mount Tsukuba about forty miles north-east of Tokyo, the third in and near the Awa-Kazusa peninsula, and the fourth round Hakone at the northern end of the Sagami-Izu peninsula. In other words, during these years, the immediate neighbourhood of Tokyo was seismically quiet, while the three mountainous regions surrounding the city at a distance of about forty miles, gave rise to "very frequent occurrences of earthquakes, which, though often sharply felt in the city, are harmless, as the districts in question do not belong to a great seismic zone." Then follows this remarkable prediction. "In the course of time, however, the seismic districts" referred to above "will become gradually quiet, while the Musashi plain and the Tokyo bay may, as a compensation, recommence its seismic activity, and may result in the production of a strong earthquake, probably just after a year of marked minimum of seismic frequency."

The last strong earthquake (that of April 26, 1922) originated, according to Prof. Omori, off the west coast of the province of Awa in the Uraga channel; and, he concludes, "the Awa-Kazusa peninsula and the Sagami earthquake regions, at present so active, form obviously one continuous system separated by the Uraga channel of small seismic frequency, and it was exactly at the latter locality that the . . . strong earthquake [of April 26, 1922] took place. It seems

natural that a district like the Awa-Kazusa peninsula, where small shocks are taking place so frequently, does not give rise to a destructive earthquake; while a neighbouring region like the Uraga channel, which belongs to the same seismic zone, but is subject for the time to a low seismic frequency, may become the source of a strong shock." So far as the evidence at our disposal will allow us to judge, it seems to me very probable that the recent earthquake originated in the Uraga channel portion of this seismic zone and at a great depth—perhaps from 20 to 30 miles or more—below the surface.

Current Topics and Events.

Several matters of interest are referred to in the report of the Council of the British Association presented at the Liverpool meeting now in session. Major-General Sir David Bruce has been unanimously nominated by the Council to fill the office of president of the Association for the year 1924–25 (Toronto Meeting). The grateful thanks of the Association has been expressed by the Council to Sir Robert Hadfield for his generous gift designed to enable necessitous students to obtain scientific books. The gift is of 50*l.* in each of three years, and that sum, for the first year, has been distributed in grants of 10*l.* to each of five universities or colleges selected by lot, namely, University College of Bangor, North Wales; University College, Cardiff; Universities of Leeds, Liverpool, and Manchester. The Council, on behalf of the Association, joined in protesting against proposed changes in the Egyptian laws relating to antiquities, and received, through the Foreign Office and the High Commissioner, the assurance that the Egyptian Government would not modify the existing law without further careful consideration of protests received. The third grant of 250*l.* from the Caird Gift for research in radioactivity (for the year ending March 24, 1924) has been made to Prof. F. Soddy. In conformity with the rules, the Council has nominated the following new members to fill vacancies caused by retirement: Prof. W. Dalby, Dr. J. S. Flett, and Mr. C. T. Heycock, leaving two vacancies to be filled by the General Committee. The Council has nominated M. le Comte de St. Périer to be an honorary corresponding member of the Association. Arrangements for the meeting in Toronto, 1924, are in progress, and the Council has appointed a committee to assist the General Officers in this matter, including Sir D. Bruce, Sir Richard Gregory, Sir William Herdman, Prof. A. W. Kirkaldy, Prof. J. C. McLennan, Sir Ernest Rutherford, Sir Charles Sherrington, and Prof. A. Smithells. The General Committee at Hull desired the Council to consider the possibility of a meeting being held in England in 1924, following and supplementary to the Toronto Meeting. The Council does not, however, see the way clear for carrying out the suggestion.

In an article on the magnetic work carried out at the Royal Observatory, Greenwich, which appeared in Nature of September 1, p. 345, reference was made to the need for the removal of the recording instruments from Greenwich. The proposal to electrify railway routes in the vicinity of the observatory rendered this course necessary, and a site on the lower slopes of Holmbury Hill, Surrey, was chosen as meeting the requirements for the new station. Considerable opposition to the scheme was aroused on the plea that the site was on common land and that the necessary buildings would deface one of the best known view-points in Surrey. We now understand from Mr. L. W. Chubb, secretary of the Commons and Footpaths Preservation Society, that an alternative site has been found near Abinger Bottom, 1½ miles from Holmbury Hill. The position is on private land and is protected from interference by building operations by Abinger and Wotton commons. It is only 2¾ miles from a railway, but the Astronomer Royal and the technical advisers of the Admiralty have accepted the site as meeting the needs of a permanent magnetic observatory where the records commenced in 1840 at Greenwich may be continued.

According to the Calcutta correspondent of the *Times*, a severe earthquake shock, lasting several minutes, was felt in Calcutta at 4 o'clock on the morning of September 10. The direction of the shock was from north-east to south-west and it extended over a wide area, slight damage to buildings being reported at Dacca, and from various stations in Assam. It is stated that the shock was the most severe since the great earthquake of 1897.

We regret to announce the death on August 23, at the age of forty-nine, of Dr. E. F. Bashford, the first director of the Imperial Cancer Research Fund.

Prof. Bohuslav Brauner, professor of chemistry in the Bohemian University, Prague, has been elected an honorary foreign member of the French Chemical Society.

The *Times* correspondent at Cairo reports that the Ministry of Public Works has decided to construct a special wing to the Cairo Museum, to cost 28,000*l.*, for the purpose of housing the objects taken from the tomb of Tutankhamen.

Summer Time will cease in Great Britain, and normal time will be restored, at 3 a.m. (Summer Time) in the morning of Sunday, September 16, when the clock will be put back to 2 a.m.

Dr. Raul Gautier, director of the Observatory and professor of astronomy and meteorology in the University of Geneva, has been elected an honorary member of the Washington Academy of Sciences, in recognition of his prominence in geodesy and his intimate connexion with scientific work in Washington.

Dr. C. M. Wenyon has been appointed director-in-chief of the Wellcome Bureau of Scientific Research in succession to Dr. Andrew Balfour, who has held that post for the past ten years. Dr. Wenyon was previously director of research in the Tropics at the institution.

ACCORDING to the Journal of the Washington Academy of Sciences, Dr. C. A. Browne has been appointed chief of the United States Bureau of Chemistry, in succession to Dr. C. L. Alsberg, who resigned in July 1921. Dr. Browne has for the past sixteen years been head of the New York Sugar Trade Laboratory, and previously was chief of the sugar laboratory at the Bureau of Chemistry.

THE Western Galleries of the Science Museum, South Kensington, will be closed to the public on and after Monday, September 17, for the purpose of transferring the collections illustrating astronomy, geodesy, meteorology, geology, chemistry, physics, mining and metallurgy to the new buildings of the Science Museum now in course of erection. These collections will be placed on exhibition as soon as galleries are available for their reception.

THE Research Station, Long Ashton, Bristol, will be open to visitors on Wednesday, September 26, when the experimental work in progress will be explained by members of the staff, and in addition some of the most recent types of spraying machines and cultivators will be shown in working order by representatives of leading firms. Demonstrations of tree-stump blasting will take place at 12.45 P.M. and 2.30 P.M. The Minister of Agriculture, Sir Robert Arthur Sanders, Bart., has intimated his intention of visiting the station on this occasion.

A *Northern News Service* message from Berlin dated August 21, which appears in the *Publishers' Circular* of September 1, states that at a meeting of the leading German publishers on August 21 it was resolved to suspend entirely the publication of scientific works. Those issued during the past few months have proved to be a drug on the market, as the people who constitute the reading public for this kind of books no longer have any money to purchase them. Even the public and university libraries can no longer afford to do so.

THE field experiments on the manuring of root crops conducted at Rothamsted Experimental Station, Harpenden, provide, at this time of the year, a striking series of demonstration plots to which the attention of all interested in agriculture is invited. The potato plots show the effects of various potash manures and of the addition of increasing quantities of sulphate of ammonia to a complete fertiliser; comparative trials are also in progress using new fertilisers. On the mangold plots, the value of town refuse can be compared with that of dung, while, on the swede plots, the effect of sulphate of ammonia supplementing phosphates, potash, and dung applied at sowing time can be seen. With white turnips, comparisons are being made of the relative values of different green manuring crops which have been ploughed in. The secretary of the Station will be glad to make arrangements for parties of farmers or others desirous of inspecting the plots, or arrangements can be made on arrival at Harpenden.

APPLICATIONS are invited for the post of assistant in the pathological laboratory at Harpenden of the Ministry of Agriculture and Fisheries. Applicants must possess an honours degree in science, or similar qualification, and be proficient in zoology and botany. Among the duties of the person appointed will be the investigation and inspection of living plants in connexion with trade. Forms of application are obtainable from the Secretary of the Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1. They must be returned, with copies of recent testimonials, by October 1.

THE monthly meteorological chart of the North Atlantic for September issued by the Meteorological Office, Air Ministry, gives details of marine meteorology of general interest to all navigators traversing the Atlantic. The information deals with winds and ocean currents, normal isobars for the month, and limits of ice, together with the charted positions of derelicts, the northern and southern limits of Trades, and the mean paths of cyclonic disturbances. There is much on these meteorological charts which will enable a commander or officer to obtain not only the normal weather conditions for his passage, but also to foresee, by comparison with his own observations, the unusual or exceptional weather, and being forewarned he can often take advantage of the weather changes he experiences. Much time has been spent in obtaining the valuable data exhibited and any ordinary navigator can easily master the information contained. On the back of the chart Capt. L. A. Brooke Smith, the marine superintendent of the Meteorological Office, gives a discussion of a West Indian hurricane which is traced from the Tropics on September 13 of last year to the south-west coast of the British Isles on September 26 and 27, passing south-east of Newfoundland on September 23. The storm was also dealt with in the U.S. *Monthly Weather Review* for September 1922. The discussion and storm track are given chiefly to show how wireless telegraphy may be usefully applied for ascertaining the movement of such a storm when the ship is at sea.

A PAPER entitled "Le scienze fisiche e matematiche nelle opere di Dante," by Francesco Vercelli, was published in the February number of the *Rivista Marittima*. The author endeavours to show the character of Dante's ideas on arithmetic, geometry, mechanics, cosmology, meteorology, and optical phenomena by means of numerous quotations from the Divine Comedy and the "Convivio." Some of these do not seem very conclusive as regards Dante's opinions about the phenomena of Nature, and are such as may be picked out from the writings of many poets; but the majority furnish good illustrations of the ideas prevalent at the beginning of the fourteenth century, of which Dante is an excellent exponent. Thus we find under the heading of mechanics nothing but the notions of Aristotle as to why a body set in motion through the air may continue to move after the moving force has ceased to act on it. The author thinks there are some slight indications of independent thought in the direction of the true laws of motion, but the passages quoted do not seem very

convincing. Dante's cosmological ideas are so closely interwoven with his great poem that it is easy enough to find passages which illustrate it (see Nature, vol. 107, p. 428). The author devotes more space to meteorological phenomena, which are frequently alluded to in the descriptions of the different localities of the mountain of Purgatory, but none of the quotations given are of any special interest.

Messrs. Baird and Tatlock have just issued their "Standard Catalogue of Scientific Apparatus, 1923. Vol. 1. Chemistry." The previous edition of this catalogue was published in 1914, and the outbreak of the War a few months after publication rendered it practically useless. The present edition is conceived on a larger scale than the earlier one, the volume before us—Chemistry—alone containing 954 pages as against 1283 pages of the full 1914 catalogue. Judging from this catalogue, manufacturers of chemical apparatus have fully recovered the paralysis caused by the sudden stoppage of German goods in 1914. Certain items are missing, such as German balances, but every type of balance is to be found in the list. Practically everything obtainable in 1914 can be purchased now, the only difference being that instead of the major proportion coming from Germany, most of the apparatus is manufactured in England. Prices are naturally higher than in 1914, in round figures, judging from the selection of a number of typical pieces of apparatus, about double; this may be regarded as a normal ratio, and excludes the idea of profiteering in this industry. Diligent search revealed one item—india-rubber tubing—at less than pre-War prices. Glass apparatus, now almost entirely of British manufacture, shows some price anomalies. Beakers are about 2·5 times pre-War, and heavy cast glass about three times, probably due to difficulties in manufacture; on the other hand, blown glass apparatus is generally less than double pre-War price. For example, an eight-bulb Young evaporator column is only advanced from 27*s.* to 35*s.* The catalogue has a good index, and reflects credit on the enterprise of the publishers.

The latest special catalogue of Mr. F. Edwards, 83 High Street, Marylebone, W.1, is No. 450, entitled "Americana." It gives particulars of nearly 500 second-hand books relating to Central and South America: geography and travel, books of views, history, natural history, antiquities, etc.

Our Astronomical Column.

The Total Solar Eclipse of September 10.—As we go to press (September 11) news reaches us from the Royal Observatory, Greenwich, that the solar corona was seen through slight cloud during the total solar eclipse of Monday, September 10, and that good photographs were obtained by Mr. Worthington at Lompoc, California.

Spectroscopic Parallaxes of Stars of Type B.—The *Astrophys. Journ.* for June contains a paper by W. S. Adams and A. H. Joy on this subject. Their research was quite independent of that by D. L. Edwards (Mon. Not. R.A.S., Nov. 1922) and is based simply on general spectral type, not on differences of intensity of particular lines. It has long been known that there is less dispersion of absolute magnitude for type B than for later types, and the authors adopt definite values for each spectral sub-division. The following is an abbreviated list of their adopted values:

Spectral Type.	Adopted Absolute Magnitude.	
	Diffuse Lines.	Sharp Lines.
	mag.	mag.
B_0	−3·1	−3·1
B_2	−1·5	−2·0
B_4	−0·6	−1·2
B_6	−0·3	−0·9
B_8	+0·1	−0·6
A_0	+0·9	+0·2
A_2	+1·7	+0·9

Adams and Joy prepared this list with the aid of 34 trigonometrical parallaxes and others derived from moving clusters, group motion, and various statistical methods.

A list then follows of the parallaxes of 300 stars, based on these values. Their spectral types are deduced from Mt. Wilson spectrograms. The Harvard types are given for comparison, and seldom differ by more than one step.

The later sub-divisions of type O have also been included, using H. H. Plaskett's notation of O_5, O_6, O_7, O_8, O_9 for the stars with dark lines that precede B_0 in the sequence. The results have been tested by plotting reduced proper motion against absolute magnitude. The function actually plotted is $0{\cdot}2m + \log \mu$, m being apparent magnitude and μ proper motion. The resulting graph is nearly a straight line, which is claimed as support for their adopted values. It is admitted that there are exceptional stars which their formulæ will not fit: on one hand, super-giants, such as Rigel; on the other, abnormally faint B-stars such as Boss 1517, for which Voûte found the trigonometrical parallax 0·074″, while the spectroscopic one is 0·005″. The authors hope that Mr. Edwards's method may serve to find the dispersion in parallax for each sub-type.

Their largest spectroscopic parallax is 0·069″ (Boss 2698), and their smallest 0·002″ (twelve stars of about the 6th magnitude).

Sunspot Activity.—There are signs of the beginning of the new cycle of activity. A double spot of appreciable size, followed by a train of small ones, entered the disc shortly before the end of August, and was seen near the west limb, flanked by a large facula, on September 9. It was S. Latitude 29°, and is the first high-latitude spot of considerable size in the new cycle, though some very small sporadic ones have been seen during the last year or more.

On September 9 there was a second group of similar type, but not quite so large, on the other side of the equator, which entered the disc about September 5.

The Mt. Wilson report had already noted that the activity in June was greater than for some months past, there being five days when two groups were on the disc, and one day when three groups were visible.

Research Items.

RODRICK, THE LAST OF THE VISIGOTH KINGS.—Dr. A. H. Krappe, under the title of "The Legend of Rodrick, the last of the Visigoth Kings, and the Ermumarich Cycle," has published an elaborate monograph in which he illustrates the mode in which a legend has become embedded in a tribal saga. He arrives at the source of the vast legendary current which contributed to swell the Spanish, French, Scandinavian, and German epic. It is recorded by Byzantine historians, by the Arabian compiler in southern Spain, by a German monkish chronicler, by a French jongleur, and by an Icelandic sagaman. When the epic form breaks down, the material is worked up anew in the ballads of southern and northern Europe, and while in Spain the people sing of the fatal passion of Don Rodrigo, in far-off Denmark they know of King Eric Glipping and his love for the marshall's wife. This scholarly monograph is a valuable contribution to the study of saga literature.

PREHISTORIC AMERICAN INDIAN DESIGN.—The figures of men and animals and geometric designs on prehistoric Indian pottery from the Mimbres Valley, New Mexico, are described by Dr. J. W. Fewkes in a monograph recently issued by the Smithsonian Institution. They are unique among the pottery from prehistoric North America, including human figures hunting, gambling, and engaged in various other occupations, animals of all kinds; and the geometric designs show many beautiful and striking combinations of carved, rectangular, and zig-zag elements, at times forming most intricate patterns. It is difficult to imagine how these ancient inhabitants of the south-west were able to achieve the accuracy and perfection of these involved designs without the aid of mechanical devices. The predominance of animal designs indicates that these largely formed the food of the ancient Mimbrenos. Most of the bowls were of the mortuary type, buried with the dead under the floors of the houses, and nearly all the bowls are "killed" or punctured, in order to serve the needs of the dead in the other world.

THE LIFE-HISTORY OF THE HORSE OXYURIS.—B. Schwartz records (*Philippine Journ. Sci.*, vol. 23, No. 1) observations on the life-history of *Oxyuris equi*, a nematode of common occurrence in the colon, cæcum, and rectum of horses. The egg develops rapidly, exposure to air being however requisite, and in four days contains a larva. When such eggs are swallowed by guinea-pigs, emergence of the larva occurs in the small intestine, the operculum present at one end of the egg being lifted or detached. No evidence of invasion by larvæ of the liver, lungs, or other organ could be found. The life-history of *O. equi* appears to be simple and direct. The author concludes that the eggs must be eliminated from the host before development can take place, and that horses become infected as the result of swallowing water or food which has become contaminated with the eggs. The larvæ hatch in the intestine, settle down in the cæcum and colon, and by successive moults attain sexual differentiation.

CRUSTACEA FROM PACIFIC ISLANDS.—The little group of atolls, of which Fanning Island is the chief, lies about a thousand miles south of the Hawaiian Islands and just north of the equator. A knowledge of its marine fauna is therefore important in attempting to delimit the Indo-Pacific region of marine zoogeography stretching east of Suez with a very uniform faunal facies which only dies out as it meets with the very different faunas of Western America, of Northern Japan, and of South Australia. As a contribution to this knowledge Mr. C. H. Edmondson offers a list of "Crustacea from Palmyra and Fanning Islands" (Bernice P. Bishop Museum, Bulletin 5, Honolulu, 1923). As the author was without access to much important literature on his subject, it is satisfactory to know that the identification of the more critical species is vouched for by Dr. Mary J. Rathbun (who describes two new species in an appendix) and Dr. Waldo L. Schmidt of Washington. One interesting species which reaches its northern limit on these islands is the tree-climbing coco-nut crab. It has been stated to occur at the Sandwich Islands, but according to the author is not found there. A sinister explanation of its absence is suggested by the remark: "On Fanning the species is becoming depleted, as it is highly prized as an article of food by the Gilbertese labourers."

CIRCULATION OF WATER IN SPONGES.—In an interesting paper on "The Relation of the Form of a Sponge to its Currents," published in the *Quarterly Journal of Microscopical Science* (vol. 67, Part II.), Dr. G. P. Bidder discusses the mechanics of the sponge-circulation. He emphasises the fact that in most sponges pressure-chambers are established whereby the velocity of the oscular flow is controlled. In dealing with the action of the flagella of the collared cells, by which the water is propelled through the canal system, he states that they appear as if labouring in thick gum, and suggests that "to understand microscopic physics it is a serviceable short-cut to think of the water as treacle." We doubt whether this idea will appeal to those who are familiar with the extraordinary rapidity of movement of cilia and flagella in general, or, to take quite a different example, the active dancing of the extremely minute particles in the vacuoles of the Desmid Closterium. A discussion of this problem by experts in physical science would be of great value to biologists.

DEVELOPMENT OF THE CORPUS LUTEUM IN COWS.—The Swiss Society of Natural Sciences has recently published as part of its fifty-sixth volume a magnificently illustrated memoir by Dr. Max Küpfer, entitled "Der normale Turnus in der Aus- und Rückbildung gelter Körper." Dr. Küpfer was formerly a pupil of Prof. E. Zschokke, who was the first to adopt the practice, now employed by the veterinarians of many different countries, of squeezing out the persistent *corpus luteum* or "yellow body" of the ovary as a means of inducing œstrus and thereby overcoming a frequent cause of sterility in cows and heifers. Dr. Küpfer's memoir deals with the gross changes in the anatomy of the ovary and more particularly the *corpus luteum* of cows at different stages, and the coloured figures, which occupy no less than twenty-eight plates, afford a very valuable guide to the variation in the appearances of the organ from the time of ovulation onwards in both pregnant and non-pregnant animals. The memoir is further illustrated by some excellent graphs, one of which represents the degrees of development and regression and the amount of overlapping of the *corpora lutea* dating from successive ovulation periods. The *corpus luteum* of pregnancy is stated to reach its maximum development at about the second month. There are also illustrations of cystic ovaries, which are another cause of sterility. We notice an error in the table on page 32, where it is incorrectly stated that according to Dr. Marshall sows do not ovulate spontaneously during œstrus. The memoir is provided with an excellent bibliography. It is issued from the scientific laboratory of the slaughter-house

at Zürich, and is one of a series on the morphology of the female reproductive organs in mammals. We understand that the histological changes in the *corpus luteum* are to be dealt with later.

ORIGIN AND EVOLUTION OF THE ELEPHANTS.—In *La Nature* for August, Depéret and Mayet give a summary of their views upon the evolution of the mammoths and elephants from the Pliocene times to the present day. The basis of this summary has already appeared this year in an important joint paper by MM. Depéret, Mayet, and Roman published in the annals of the University of Lyons. This paper, which deals with *Elephas planifrons* and the Pliocene elephants of Europe and North Africa generally, is fully illustrated in the excellent manner usual to the publications of the University. The authors make a step forward in the division of the genus Elephas, which they now separate into eight phyletic lines which themselves fall into five groups, *i.e.* those typified by *E. meridionalis, E. antiquus, and E. primigenius* (the mammoth), all of which lines became extinct by the end of the quaternary period; and by the living forms *E. indicus*, a line which is descended from *E. namadicus*, and finally, *E. africanus*, a line of unknown ancestry. The authors agree in large measure with Osborn's view that the group is polyphyletic, but, while cutting out the genus Stegodon from any close connexion with the African elephant, go further than Osborn in the subdivision of the others.

EARLY PALÆOZOIC PLANTS IN AUSTRALIA.—Recent exploration in the mountains along the Walhalla line, in Gippsland, Victoria, shows that the earliest flora of a definite structural type, largely representing the Procormophyta, is well developed in rocks that appear to range from Upper Silurian to Upper Devonian. The Silurian graptolite, Monograptus, occurs in some of these beds, while in others the association of the molluscs Panenka and Styliola with the plants seems to suggest that the bulk of the series is Devonian. Thursophyton and Haliserites (Psilophyton) are typical components of this flora. Both the flora and fauna of these interesting beds are now being worked out by a graduate of the University of Melbourne in conjunction with Mr. F. Chapman, the palæontologist of the National Museum. A detailed comparison with the Rhynie flora should throw much light on the early history of the vegetable kingdom.

DEFECTS IN COLOUR PHOTOGRAPHS.—It is well known that in the photographic reproduction of colours there are certain defects which can only be eliminated by fine etching, that is, re-etching certain *parts* of the three plates, as shown to be necessary to the skilled workman. These outstanding defects of the three-colour process have been fully investigated by Mr. A. J. Bull, and his results are described in the current number of the Journal of the Royal Photographic Society. His method was to measure the spectra of certain colours and compare their curves with those of the same colours as reproduced. The errors are due to the inks used, and are summarised as follows:—Blues and greens become darker and greyer. Blue-greens lose their greenish hue. Pinks acquire a yellow hue. Mauves become brown. Reds lose any bluish tint that they may possess. Yellows are lightened without change of hue, but oranges and browns are well reproduced. There is a tendency for the middle tones of a black to white scale to become reddish. The lightening of yellows is due to the yellow ink being very light. The inks are transparent enough to allow of the approximate calculation of the visual effect of their superposition. There seems to be little immediate hope of getting printing inks of the theoretically correct character.

POSITIVE RAYS AND THE POLAR AURORA.—In the *Physikalische Zeitschrift* of July 1, Herr H. Bongards reviews some of the available evidence as to the nature of the aurora, and is inclined to favour the view that it is caused by highly-charged, positive argon particles, sent out with very high velocity from the sun. The well-known green line, which appears to be identical with that discovered by Wiechert in the night sky of middle latitudes, has a wave length which agrees, within the limits of observational error, with a bright line in the blue spectrum of argon, and can scarcely be the same as a faint line in the multiple-lined hydrogen spectrum. There are also two bright lines in the spectrum of the red portions of the aurora, the wave lengths of which were determined with fair accuracy by Vogel in 1871; they agree with those of two lines in the red spectrum of argon; and, while further investigation is desirable, the evidence that argon is concerned in the polar aurora seems worthy of consideration. Bongards does not consider it impossible that argon exists in the air at the height of the aurora; and suggests that it may possibly be carried up by volcanic eruptions. He, however, leans strongly to the view that argon particles (possibly nuclei without external electrons) are ejected by the sun with very high velocities, which enable them to penetrate deep into the earth's atmosphere. Since they have none of the electrons concerned in radiation, they cannot emit light until, by repeated collision with air molecules, they have lost sufficient velocity to enable them to pick up the necessary electrons; this does not occur until the velocity is so low that the Doppler effect, which appears to be small in monatomic gases, cannot be noticed.

CELLULOSE ACETATE.—The *Chemical Trade Journal* for August 10 contains an article on cellulose acetate, a material which was first prepared by Schutzenberger in 1865, but remained a curiosity until Cross (1894) obtained it by the action of acetyl chloride and zinc acetate on cellulose. Cellulose acetate is the basis of aeroplane "dope" (it renders taut the fabric on the wings), lacquers, non-flaming celluloid materials, etc. These applications are described fully in the article, together with the more recent processes of manufacture and the important question of suitable solvents for the acetate.

THE PATHS OF ELECTRONS IN SOLUTION.—A paper on this subject, by L. Pisarjevski and M. Rosenberg, appears in the Jour. Russ. Phys.-Chem. Soc. (1923, 54, 533-547). When potassium iodide solutions are electrolysed, using spark electrodes, potassium hydroxide and iodine are liberated at each electrode. If starch paste be added to such solutions, a blue streak appears at the passage of each spark, which may go vertically through the solution for a distance of 9 cm., if a commutator be used, and then spreads out. The addition of phenolphthalein to the solutions produces a red streak under these conditions, which follows a more zig-zag path than the blue one, and also spreads out at its greatest depth, the coloration in both cases disappearing in about 30 seconds. These streaks may be deviated by applying a magnetic field to the solutions. The above phenomenon is explained as being due to the passage of high velocity electrons from the electrodes into the solutions; the concussion of these electrons with iodine ions liberates further electrons which again collide with ions in solution, and leave the iodine as free atoms. The free electrons also combine with potassium ions, neutralising their positive charges, and producing free potassium. It is thus possible visually to demonstrate that processes of oxidation involve the loss of electrons, and the reverse.

Brazilian Meteorological Service, 1921–23.

A SHORT report issued by Dr. Sempais Ferraz, the director of the Brazilian Meteorological Service, contains an account of the work accomplished under his auspices since its inauguration as an independent service in June 1921. Prior to this date, meteorological activities in Brazil were carried out by departments primarily constituted for some other purpose, and were confined to researches in pure climatology. What little forecasting was done was available only in the capital. No publications were issued except the Year-book for 1910 and "Instructions to Observers." With the progress of meteorology and the resulting rapid creation of new services, this dependence became impossible, and in June 1921 an independent meteorological service was established.

The numbers of second- and third-order climatological stations have been increased from 51 and 46 to 74 and 78 respectively. Rainfall stations and co-operative stations, of which there were 31 and 26 respectively in May 1921, now number 57 and 180. Inspections which were previously almost non-existent are now actively carried out all over the country. Year-books have been published for each of the years 1911–18, and those for 1919 and 1920 are in the press, while a book of Normals has also been issued. Whereas no data were published in the newspapers prior to 1921, each station is now obliged to publish fortnightly reports, and those stations that are located in capitals of States issue daily weather summaries.

Daily forecasts for the Southern States, based on synoptic data from 80 stations in Brazil, 18 in the Argentine, and 6 in Uruguay, are distributed from Rio de Janeiro and St. Paulo by telegraph or telephone. Two additional distributive centres are being established this year in St. Catherina and Parana. Forecasts are broadcasted by radio-telephone from Corcavado, while Rio's radio station sends out synoptic data and forecasts for the night and following days. A storm-signal service is in operation along the coast, and every four hours the coastal radio stations, 12 in number, broadcast the weather at the time. In the large towns flags are used to indicate the probable weather. Owing to the topographical conditions of the country, long experience is required in dealing with wind and pressure data. Empirical rules have had to be devised to meet the special circumstances. These are to be described in a forthcoming memoir entitled "Forecasting in Brazil."

Provision is being made for the study of agricultural meteorology by the establishment of stations modelled on those which formerly existed in Russia. There are at present eight of these stations in operation. A ten-days' bulletin is now published in all the leading newspapers, setting out the condition of the most important crops, pasture lands, and roads. Abridged reports are published monthly in the magazines. Phenological observations are also made.

All the rainfall data are under revision, and an atlas is to be published shortly which will include a general discussion of the different zonal dry and wet seasons. A flood service for the Parahyba river has been inaugurated, and a similar service is being arranged for the Amazon, where floods occasion considerable destruction amongst cattle.

Pilot-balloon observations are now made at seven stations. The establishment of a kite station in Alegrete (Rio Grande do Sul) is expected to reveal interesting data of the secondary circulation in a region which Brazilian meteorologists have described as the "turn-table" of moving highs and a frequent path of outgoing depressions. A second kite station to be established at Ceara is expected to furnish an explanation of the curious irregular droughts of north-eastern Brazil and a possible method of forecasting them. It is hoped that the pursuit of aerological research in Brazil, besides its practical assistance to aviation, "will help the eminent meteorologists of the world in their search for the missing links of general dynamic theories of the atmosphere."

This record of twenty months' work is all the more gratifying when account is taken of the difficulties which, as the author points out, beset meteorological activity in Brazil. Brazil has a highly intellectual *élite*, but the mass of the people have scarcely any education. Observers have to be paid, as voluntary co-operation at present is unavailable. P. I. M.

Sir Isaac Newton and the S.P.C.K.

SOME recent references which a correspondent has recently had occasion to make to Thomas Hollis's "Memoirs," published in 1780 (4to, 2 vols.), have led to the unearthing by him of an interesting draft letter attributed to Sir Isaac Newton, of which no mention is made in Brewster's "Life." The chronicler relates that, in September 1764, Mr. Hawksbee, son of Mr. Hawksbee, sometime clerk to the Royal Society, waited upon Mr. Hollis with the copy of a paper written by Sir Isaac Newton, containing minutes of his opinion against a proposal which had been made to the Royal Society to accommodate the members of the Society for Promoting Christian Knowledge, then newly instituted, with the use of the Society's house for its meetings. Mr. Hawksbee, the father, had shown Hollis the original in Sir Isaac's own handwriting, but could not be prevailed on to part with it. He goes on to say that Hollis was glad, however, to obtain a copy in Hawksbee's handwriting, from his son, a soldier in the artillery.

In 1698–9 the S.P.C.K. was beginning to take definite shape as a result of the efforts of a small band of enthusiasts. Indeed, a tentative plan of constitution was put forward about then by Dr. Bray, who suggested that "these persons" be incorporated by charter as [like] the Royal Society, and Sons of the Clergy; and be thereby empowered to "meet and consult as often as there shall be occasion." Sir Isaac's letter was drawn up apparently while the Royal Society was in occupation at Gresham College, and in the early days of the S.P.C.K. Sir Isaac says, "I never heard of them before."

Subjoined is the letter referred to above. Its terms are of singular interest as a defence against encroachment:

"We have a reputation abroad, and the Society for Promoting Christian Knowledge, are scarce known at home; I never heard of them before. And to admit them into our bosom would be, in a little time, to share our reputation with them.

"We are incorporated by the crown; and to herd ourselves with a club not yet incorporated, would be ingratitude to our Founder.

"Our house was built by benefactions; and to divert it to other uses than our benefactors intended would be ingratitude to their memory; and a discouragement to future benefactions.

"If we once lend our house, time will make custom,

and custom will give right: It is easier to deny in the beginning than afterward.

"It is a fundamental rule of the Society not to meddle with religion; and the reason is, that we may give no occasion to religious bodies to meddle with us.

"The Society for Promoting Christian Knowledge, have a splendid title, but we are to regard not names, but things. If all their members are not men of exemplary lives and conversation, some of them, by misdemeanors, may bring reflections upon us; and why should we run the hazard?

"If we comply, we may dissatisfy some of those that are against it; especially those that are of other religions, and make them leave our meetings, which are already too thin.

"There are many vestries in London; and it is more proper for a religious society to meet in a vestry or —— than in the house of a society which is mixed of men of all religions, and meddles with none.

"Those of the Christian Society have dining rooms of their own, and may lend them by turns to their meetings. And the tenth commandment is, 'Thou shalt not covet thy neighbour's house.'

"This proposal can be of no advantage to us; but may prove disadvantageous; and we have, all of us, at our admission, promised, under our hands, to consult the good of the society; and ought not to break the fundamental covenant upon which we were admitted."

Mechanism of Stomatal Movement in Plants.

IT has been generally recognised for a long time past that the stomata of the leaf opened when more water was absorbed by the guard cells and closed when water passed from the guard cells into the surrounding tissues. It is also frequently assumed that the mechanism by which this water exchange takes place must be associated with the presence of green chloroplasts in the guard cells, the other epidermal cells being usually free from chlorophyll.

The mechanism by which the osmotic concentration of the cell sap of the guard cell is controlled has, however, remained obscure; of late years experimental work has thrown light upon this problem, and a valuable summary of this work is given by Friedl Weber in *Die Naturwissenschaften*, Vol. 11, Heft 17, April 27. Lloyd's work had shown that the movement of the guard cells is not connected with the direct photosynthesis of carbon dioxide by the guard cells, the cells around the closed stoma at night being packed with starch, while in the early morning, in daylight, the starch rapidly hydrolyses and the stoma opens.

Iljin's series of papers now suggest that the varying activity of diastatic enzymes under different conditions are intimately associated with the stomatal mechanism. Iljin showed that with stomata closed the guard cells were usually full of starch, the starch disappearing as the stomata open. Further experiments showed that sodium and potassium salts accelerated starch hydrolysis, while calcium salts prevented it; inorganic anions produced less effect, but citrates and acetates exerted considerable effect.

The effect of the various salts upon the reaction of the cell has to be carefully considered, the slightest increase in hydrion concentration favouring starch hydrolysis and stomatal opening; the slightest decrease, starch accumulation and stomatal closure. The reaction of a stoma to these various factors differs with the plant, halophytes, for example, showing themselves very insensitive to changes in salt concentration, while a plant like *Rumex acetosa*, with very acid sap, is especially sensitive. It is clear that our conception of the mechanism of control of stomatal aperture will require re-examination in the light of this interesting work. Thus Linsbauer's observations on the movement of the guard cells with change of light intensity, or with alterations in the carbon dioxide content of the air, may find their explanation in the consequent alteration of reaction in the cell sap of the guard cell.

University and Educational Intelligence.

DURHAM.—As a result of the recent decision of the council of Armstrong College to build a College Library, all practising members of the Northern Architectural Association, and a few architects in other parts of Great Britain, were invited to submit competitive designs for the building. The first premium has been awarded to Mr. A. Dunbar Smith, who has been appointed architect of the library, and work will proceed forthwith. The building will consist of a reading-room seating 122 readers, storage space for 175,000 volumes, with accommodation for 55 research students, administrative rooms, and photographic laboratory, and is so designed that additional storage space for 60,000 volumes may be added when required.

MANCHESTER.—On Tuesday, September 11, Sir George Beilby opened the new buildings to be occupied by the Department of Metallurgy in the University. Although founded in 1906, the home of the Department has so far been merely a few laboratories loaned by the Chemistry Department. Especially from the point of view of the research workers this arrangement was far from satisfactory. In the new buildings four research laboratories will be available, in addition to general laboratories for pyrometry, mechanical testing, and metallography. A small foundry and machinery room together with the heat-treatment laboratory will further offer facilities both for teaching and research which have hitherto been incompletely available. The main general laboratory, named after Henry Cort, the eighteenth-century metallurgist, the inventor of rolling metals in grooved rolls and a pioneer in connexion with the puddling process, is well equipped for the determination of the physical properties of metals at temperatures above the normal. A small laboratory is devoted to fuel examinations, so that it may be claimed that the new buildings afford excellent facilities for both teaching and research in metallurgy, metallography, and fuel. Since 1910 sixty papers have been published in recognised journals dealing with the research work done in the Department. Among the more important of the subjects investigated may be cited work on high-speed steel, the growth of cast iron on repeated heatings, chromium steels, including stainless steel, the influence of gases on iron and steel, the production of high-pressure castings, and the hardness and elastic limits of metals both at and above room temperatures. On the foundation laid by Prof. H. B. Dixon and continued by his successors in the chair of metallurgy, Profs. H. C. H. Carpenter and C. A. Edwards, an edifice worthy of their labours has at length been erected.

THE following free public Gresham lectures will be delivered at Gresham College, Basinghall Street, E.C., at 6 o'clock on the dates given: Astronomy, by A. R. Hinks, on October 9, 10, 11, and 12; Physic, by Sir Robert Armstrong-Jones, on October 16, 17, 18, and 19; and Geometry, by W. H. Wagstaff, on October 23, 24, 25, and 26.

Societies and Academies.

PARIS.

Academy of Sciences, August 20.—M. Guillaume Bigourdan in the chair.—A. **Lacroix**: The constitution of the Rockall bank. The island of Rockall emerges from a submarine bank defined by depths of 183 metres, and measures about 70 miles. Blocks of basalt have been frequently found on this bank by fishermen and by systematic dredging. Two views have been put forward as to the origin of these blocks. Forbes suggested transportation by glaciers from Iceland or Jan Mayen island, but G. A. J. Cole considers them as constituting the debris of a submerged basaltic plateau, and this view was accepted by Judd. Detailed examination and chemical analysis of the rocks collected by Charcot in 1921 on the Rockall bank confirms Cole's hypothesis.—Charles **Richet**: The influence of removal of the spleen in cases of insufficient feeding. Details of experiments lasting 126 days on five dogs without spleens and four normal dogs, as controls.—Paul **Vuillemin**: Variation and fluctuation in the number of stigmata of Papaver.—Charles **Nordmann**: The mechanism of hovering flight and the morphology of hovering birds.—N. Vasilesco **Karpen**: The electromotive force of batteries, chemical affinity, and molecular attraction. The formulæ for the E.M.F. of a Daniell cell given by Nernst and by Helmholtz are regarded by the author as inconsistent, and other objections are raised against the Nernst expression. A modified Nernst theory is proposed based on the Laplacian attraction exerted on the molecules and ions situated at the level of the surface of separation between two different media.—L. **Bert**: The preparation and application to organic syntheses of the magnesium derivative of *p*-bromcumene. *p*-Bromcumene has not hitherto been utilised in syntheses by the Grignard reaction, on account of its high price. Recently, isopropyl alcohol has been obtainable commercially at a low price, and this can readily be converted into isopropyl bromide, cumene, and *p*-bromcumene, with good yields. Details are given of the best method of preparing the magnesium compound of *p*-bromcumene and of some compounds prepared by means of it.—G. **Vavon** and D. **Ivanoff**: Catalytic hydrogenation and steric hindrance. The study of some nonanones. Four saturated C_9 ketones were studied, dipropylacetone, methylethylpropylacetone, dimethyldiethylacetone, and hexamethylacetone. Both the formation of oxims, and of phenylhydrazones, as well as the catalytic hydrogenation of the ketones in the presence of platinum, follow the law of steric hindrance.—P. **Lebeau**: The quantity and the nature of the gases evolved by solid combustibles under the action of heat in a vacuum: anthracites. The volume of gas given by various combustibles is not a function of the percentage of volatile matter. Anthracites, poor in volatile matter, give volumes of gas of the same order as bituminous coals. The gas from anthracite contains high proportions of hydrogen.—M. de **Rohan-Chabot**: Magnetic measurements in Angola and in Rhodesia by the Rohan-Chabot expedition. Observations taken in 1912 and 1913 at 44 stations in Angola and 3 in Rhodesia are given in tabular form.—Fernand **Chodat** and A. **Kotzareff**: The difference between pathological and normal sera and the autophylactic property of the latter.—A. **Paillot**: A new flagellosis of an insect and a process of natural infection not hitherto described.—C. **Levaditi** and S. **Nicolau**: The persistence of the neurovaccine in the testicle, the ovary, and the lung of animals having acquired anti-vaccinal immunity.

SYDNEY

Royal Society of New South Wales, July 4.—Mr. R. H. Cambage, president, in the chair.—G. J. **Burrows** and F. **Eastwood**: Molecular solution volumes in ethyl alcohol. The authors have measured the densities of alcoholic solutions of various organic compounds, and calculated their molecular solution volumes. It has been found that the solution of a non-associated solute in alcohol causes a contraction in volume of 20 c.c. per gram molecule of solute, and that a smaller contraction indicates that the solute is associated in the liquid state.—E. **Cheel**: Two additional species of Leptospermum. Two additional species of plants belonging to the tea-tree group were described. One species, namely, *Leptospermum coriaceum*, was originally described by Baron von Mueller as a distinct species, but was afterwards merged as a synonym with the common "sand stay" or coastal tea-tree of N. S. Wales (*L. lævigatum*). Certain structural characters, however, as well as geographical range from Sandringham in Victoria through Murray Bridge in S. Australia to Ooldea on the Transcontinental Line, serve to distinguish this species. The second species, which may be called the "small-fruited tea-tree" (*L. microcarpum*) is confined chiefly to the northern parts of N. S. Wales and Queensland. It has smooth whip-stick-like branches, and sheds its bark like some of the gum-trees.—A. R. **Penfold**: The essential oils of *Callistemon lanceolatus* and *C. viminalis*. The essential oils from two well-known "bottle brushes," *Callistemon lanceolatus* and *C. viminalis*, were described. The former inhabits the swampy situations of the coast extending to about Gloucester, while the latter is a denizen of the banks of the rivers of the far north coast and extends into Queensland. The essential oils were of a pale yellow colour, and were practically identical with a medicinal eucalyptus oil. Unfortunately, the low percentage yield of oil, 0·2 per cent., precludes their successful exploitation, despite their abundance, on account of the higher yield of 2 to 3 per cent. obtainable from the eucalypts.

Supplement to NATURE

No. 2811 . SEPTEMBER 15, 1923

The Electrical Structure of Matter.[1]

By Prof. Sir ERNEST RUTHERFORD, D.Sc., LL.D., Ph.D., F.R.S., President of the British Association.

IT was in 1896 that this Association last met in Liverpool, under the presidency of the late Lord Lister, that great pioneer in antiseptic surgery, whose memory is held in affectionate remembrance by all nations. His address, which dealt mainly with the history of the application of antiseptic methods to surgery and its connexion with the work of Pasteur, that prince of experimenters, whose birth has been so fittingly celebrated this year, gave us in a sense a completed page of brilliant scientific history. At the same time, in his opening remarks, Lister emphasised the importance of the discovery by Röntgen of a new type of radiation, the X-rays, which we now see marked the beginning of a new and fruitful era in another branch of science.

The visit to Liverpool in 1896 was for me a memorable occasion, for it was here that I first attended a meeting of this Association, and here that I read my first scientific paper. But of much more importance, it was here that I benefited by the opportunity, which these gatherings so amply afford, of meeting for the first time many of the distinguished scientific men of Great Britain and the foreign representatives of science who were the guests of this city on that occasion. The year 1896 has always seemed to me a memorable one for other reasons, for on looking back with some sense of perspective we cannot fail to recognise that the last Liverpool meeting marked the beginning of what has been aptly termed the heroic age of physical science. Never before in the history of physics has there been witnessed such a period of intense activity when discoveries of fundamental importance have followed one another with such bewildering rapidity.

The discovery of X-rays by Röntgen had been published to the world in 1895, while the discovery of the radioactivity of uranium by Becquerel was announced early in 1896. Even the most imaginative of our scientific men could never have dreamed at that time of the extension of our knowledge of the structure of matter that was to develop from these two fundamental discoveries, but in the records of the Liverpool meeting we see the dawning recognition of the possible consequences of the discovery of X-rays, not only in their application to medicine and surgery, but also as a new and powerful agent for attacking some of the fundamental problems of physics. The address of Sir J. J. Thomson, president of Section A, was devoted mainly to a discussion of the nature of the X-rays, and the remarkable properties induced in gases by the passage of X-rays through them—the beginning of a new and fruitful branch of study.

In applied physics, too, this year marked the beginning of another advance. In the discussion of a paper which I had the honour to read, on a new magnetic detector of electrical waves, the late Sir William Preece told the meeting of the successful transmission of signals for a few hundred yards by electric waves which had been made in England by a young Italian, G. Marconi. The first public demonstration of signalling for short distances by electric waves had been given by Sir Oliver Lodge at the Oxford Meeting of this Association in 1894. It is startling to recall the rapidity of the development from such small beginnings of the new method of wireless intercommunication over the greatest terrestrial distances. In the last few years this has been followed by the even more rapid growth of the allied subject of radiotelephony as a practical means of broadcasting speech and music to distances only limited by the power of the transmitting station. The rapidity of these technical advances is an illustration of the close interconnexion that must exist between pure and applied science if rapid and sure progress is to be made. The electrical engineer has been able to base his technical developments on the solid foundation of Maxwell's electromagnetic theory and its complete verification by the researches of Hertz, and also by the experiments of Sir Oliver Lodge in the University of Liverpool—a verification completed long before the practical possibilities of this new method of signalling had been generally recognised. The later advances in radiotelegraphy and radiotelephony have largely depended on the application of the results of fundamental researches on the properties of electrons, as illustrated in the use of the thermionic valve or electron tube which has proved such an invaluable agent for both the transmission and reception of electric waves.

It is of great interest to note that the benefits of this union of pure and applied research have not been one-sided. If the fundamental researches of the workers in pure science supply the foundations on which the applications are surely built, the successful practical application in turn quickens and extends the interest of the investigator in the fundamental problem, while the development of new methods and appliances required for technical purposes often provides the investigator with means of attacking still more difficult questions. This important reaction between pure and applied science can be illustrated in many branches of knowledge. It is particularly manifest in the industrial development of X-ray radiography for therapeutic and industrial purposes, where the development on a large scale of special X-ray tubes and improved methods of excitation has given the physicist much more efficient tools to carry out his researches on the nature of the rays themselves and on the structure of the atom. In this age no one can draw any sharp line of distinction

[1] Inaugural address delivered to the British Association at Liverpool on September 12.

between the importance of so-called pure and applied research. Both are equally essential to progress, and we cannot but recognise that without flourishing schools of research on fundamental matters in our universities and scientific institutions technical research must tend to wither. Fortunately there is little need to labour this point at the moment, for the importance of a training in pure research has been generally recognised. The Department of Scientific and Industrial Research has made a generous provision of grants to train qualified young men of promise in research methods in our scientific institutions, and has aided special fundamental researches which are clearly beyond the capacity of a laboratory to finance from its own funds. Those who have the responsibility of administering the grants in aid of research for both pure and applied science will need all their wisdom and experience to make a wise allocation of funds to secure the maximum of results for the minimum of expenditure. It is fatally easy to spend much money in a direct frontal attack on some technical problem of importance when the solution may depend on some addition to knowledge which can be gained in some other field of scientific inquiry possibly at a trifling cost. It is not in any sense my purpose to criticise those bodies which administer funds for fostering pure and applied research, but to emphasise how difficult it is to strike the correct balance between the expenditure on pure and applied science in order to achieve the best results in the long run.

It is my intention here to refer very briefly to some of the main features of that great advance in knowledge of the nature of electricity and matter which is one of the salient features of the interval since the last meeting of this Association in Liverpool.

In order to view the extensive territory which has been conquered by science in this interval, it is desirable to give a brief summary of the state of knowledge of the constitution of matter at the beginning of this epoch. Ever since its announcement by Dalton the atomic theory has steadily gained ground, and formed the philosophic basis for the explanation of the facts of chemical combination. In the early stages of its application to physics and chemistry it was unnecessary to have any detailed knowledge of the dimensions or structure of the atom. It was only necessary to assume that the atoms acted as individual units, and to know the relative masses of the atoms of the different elements. In the next stage, for example, in the kinetic theory of gases, it was possible to explain the main properties of gases by supposing that the atoms of the gas acted as minute perfectly elastic spheres. During this period, by the application of a variety of methods, many of which were due to Lord Kelvin, rough estimates had been obtained of the absolute dimensions and mass of the atoms. These brought out the minute size and mass of the atom and the enormous number of atoms necessary to produce a detectable effect in any kind of measurement. From this arose the general idea that the atomic theory must of necessity for ever remain unverifiable by direct experiment, and for this reason it was suggested by one school of thought that the atomic theory should be banished from the teaching of chemistry, and that the law of multiple proportions should be accepted as the ultimate fact of chemistry.

While the vaguest ideas were held as to the possible structure of atoms, there was a general belief among the more philosophically minded that the atoms of the elements could not be regarded as simple unconnected units. The periodic variations of the properties of the elements brought out by Mendeléeff were only explicable if atoms were similar structures in some way constructed of similar material. We shall see that the problem of the constitution of atoms is intimately connected with our conception of the nature of electricity. The wonderful success of the electromagnetic theory had concentrated attention on the medium or ether surrounding the conductor of electricity, and little attention had been paid to the actual carriers of the electric current itself. At the same time the idea was generally gaining ground that an explanation of the results of Faraday's experiments on electrolysis was only possible on the assumption that electricity, like matter, was atomic in nature. The name "electron" had even been given to this fundamental unit by Johnstone Stoney, and its magnitude roughly estimated, but the full recognition of the significance and importance of this conception belongs to the new epoch.

For the clarifying of these somewhat vague ideas, the proof in 1897 of the independent existence of the electron as a mobile electrified unit, of mass minute compared with that of the lightest atom, was of extraordinary importance. It was soon seen that the electron must be of a constituent of all the atoms of matter, and that optical spectra had their origin in their vibrations. The discovery of the electron and the proof of its liberation by a variety of methods from all the atoms of matter was of the utmost significance, for it strengthened the view that the electron was probably the common unit in the structure of atoms which the periodic variation of the chemical properties had indicated. It gave for the first time some hope of the success of an attack on that most fundamental of all problems—the detailed structure of the atom. In the early development of this subject science owes much to the work of Sir J. J. Thomson, both for the boldness of his ideas and for his ingenuity in developing methods for estimating the number of electrons in the atom, and in probing its structure. He early took the view that the atom must be an electrical structure, held together by electrical forces, and showed in a general way lines of possible explanation of the variation of physical and chemical properties of the elements, exemplified in the periodic law.

In the meantime our whole conception of the atom and of the magnitude of the forces which held it together were revolutionised by the study of radioactivity. The discovery of radium was a great step in advance, for it provided the experimenter with powerful sources of radiation specially suitable for examining the nature of the characteristic radiations which are emitted by the radioactive bodies in general. It was soon shown that the atoms of radioactive matter were undergoing spontaneous transformation, and that the characteristic radiations emitted, namely, the α-, β-, and γ-rays, were an accompaniment and consequence of these atomic explosions. The wonderful succession of changes that occur in uranium and thorium, more

than thirty in number, was soon disclosed and simply interpreted on the transformation theory. The radioactive elements provide us for the first time with a glimpse into Nature's laboratory, and allow us to watch and study, but not to control, the changes that have their origin in the heart of the radioactive atoms. These atomic explosions involve energies which are gigantic compared with those involved in any ordinary physical or chemical process. In the majority of cases an α-particle is expelled at high speed, but in others a swift electron is ejected often accompanied by a γ-ray, which is a very penetrating X-ray of high frequency. The proof that the α-particle is a charged helium atom for the first time disclosed the importance of helium as one of the units in the structure of the radioactive atoms, and probably also in that of the atoms of most of the ordinary elements. Not only then have the radioactive elements had the greatest direct influence on natural philosophy, but in subsidiary ways they have provided us with experimental methods of almost equal importance. The use of α-particles as projectiles with which to explore the interior of the atom has definitely exhibited its nuclear structure, has led to artificial disintegration of certain light atoms, and promises to yield more information yet as to the actual structure of the nucleus itself.

The influence of radioactivity has also extended to yet another field of study of fascinating interest. We have seen that the first rough estimates of the size and mass of the atom gave little hope that we could detect the effect of a single atom. The discovery that the radioactive bodies expel actual charged atoms of helium with enormous energy altered this aspect of the problem. The energy associated with a single α-particle is so great that it can readily be detected by a variety of methods. Each α-particle, as Sir William Crookes first showed, produces a flash of light easily visible in a dark room when it falls on a screen coated with crystals of zinc sulphide. This scintillation method of counting individual particles has proved invaluable in many researches, for it gives us a method of unequalled delicacy for studying the effects of single atoms. The α-particle can also be detected electrically or photographically, but the most powerful and beautiful of all methods is that perfected by Mr. C. T. R. Wilson for observing the track through a gas, not of an α-particle alone, but of any type of penetrating radiation which produces ions or of electrified particles along its path. The method is comparatively simple, depending on the fact, first discovered by him, that if a gas saturated with moisture is suddenly cooled each of the ions produced by the radiation becomes the nucleus of a visible drop of water. The water-drops along the track of the α-particle are clearly visible to the eye, and can be recorded photographically. These beautiful photographs of the effect produced by single atoms or single electrons appeal, I think, greatly to all scientific men. They not only afford convincing evidence of the discrete nature of these particles, but also give us new courage and confidence that the scientific methods of experiment and deduction are to be relied upon in this field of inquiry; for many of the essential points brought out so clearly and concretely in these photographs were correctly deduced long before such confirmatory photographs were available. At the same time, a minute study of the detail disclosed in these photographs gives us most valuable information and new clues on many recondite effects produced by the passage through matter of these flying projectiles and penetrating radiations.

In the meantime a number of new methods had been devised to fix with some accuracy the mass of the individual atom and the number in any given quantity of matter. The concordant results obtained by widely different physical principles gave great confidence in the correctness of the atomic idea of matter. The method found capable of most accuracy depends on the definite proof of the atomic nature of electricity and the exact valuation of this fundamental unit of charge. We have seen that it was early surmised that electricity was atomic in nature. This view was confirmed and extended by a study of the charges carried by electrons, α-particles, and the ions produced in gases by X-rays and the rays from radioactive matter. It was first shown by Townsend that the positive or negative charge carried by an ion in gases was invariably equal to the charge carried by the hydrogen ion in the electrolysis of water, which we have seen was assumed, and assumed correctly, by Johnstone Stoney to be the fundamental unit of charge. Various methods were devised to measure the magnitude of this fundamental unit; the best known and most accurate is Millikan's, which depends on comparing the pull of an electric field on a charged droplet of oil or mercury with the weight of the drop. His experiments gave a most convincing proof of the correctness of the electronic theory, and gave a measure of this unit, the most fundamental of all physical units, with an accuracy of about one in a thousand. Knowing this value, we can by the aid of electrochemical data easily deduce the mass of the individual atoms and the number of molecules in a cubic centimetre of any gas with an accuracy of possibly one in a thousand, but certainly better than one in a hundred. When we consider the minuteness of the unit of electricity and of the mass of the atom, this experimental achievement is one of the most notable even in an era of great advances.

The idea of the atomic nature of electricity is very closely connected with the attack on the problem of the structure of the atom. If the atom is an electrical structure it can only contain an integral number of charged units, and, since it is ordinarily neutral, the number of units of positive charge must equal the number of negative. One of the main difficulties in this problem has been the uncertainty as to the relative part played by positive and negative electricity in the structure of the atom. We know that the electron has a negative charge of one fundamental unit, while the charged hydrogen atom, whether in electrolysis or in the electric discharge, has a charge of one positive unit. But the mass of the electron is only 1/1840 of the mass of the hydrogen atom, and though an extensive search has been made, not the slightest evidence has been found of the existence of a positive electron of small mass like the negative. In no case has a positive charge been found associated with a mass less than that of the charged atom of hydrogen. This difference between positive and negative electricity is at first sight very surprising, but the deeper we pursue our inquiries the more this fundamental difference

between the units of positive and negative electricity is emphasised. In fact, as we shall see later, the atoms are quite unsymmetrical structures with regard to the positive and negative units contained in them, and indeed it seems certain that if there were not this difference in mass between the two units, matter, as we know it, could not exist.

It is natural to inquire what explanation can be given of this striking difference in mass of the two units. I think all scientific men are convinced that the small mass of the negative electron is to be associated entirely with the energy of its electrical structure, so that the electron may be regarded as a disembodied atom of negative electricity. We know that an electron in motion, in addition to possessing an electric field, also generates a magnetic field around it, and energy in the electromagnetic form is stored in the medium and moves with it. This gives the electron an apparent or electrical mass, which, while nearly constant for slow speeds, increases rapidly as its velocity approaches that of light. This increase of mass is in good accord with calculation, whether based on the ordinary electrical theory or on the theory of relativity. Now we know that the hydrogen atom is the lightest of all atoms, and is presumably the simplest in structure, and that the charged hydrogen atom, which we shall see is to be regarded as the hydrogen nucleus, carries a unit positive charge. It is thus natural to suppose that the hydrogen nucleus is the atom of positive electricity, or positive electron, analogous to the negative electron, but differing from it in mass. Electrical theory shows that the mass of a given charge of electricity increases with the concentration, and the greater mass of the hydrogen nucleus would be accounted for if its size were much smaller than that of the electron. Such a conclusion is supported by evidence obtained from the study of the close collisions of α-particles with hydrogen nuclei. It is found that the hydrogen nucleus must be of minute size, of radius less than the electron, which is usually supposed to be about 10^{-13} cm.; also the experimental evidence is not inconsistent with the view that the hydrogen nucleus may actually be much smaller than the electron. While the greater mass of the positive atom of electricity may be explained in this way, we are still left with the enigma why the two units of electricity should differ so markedly in this respect. In the present state of our knowledge it does not seem possible to push this inquiry further, or to discuss the problem of the relation of these two units.

We shall see that there is the strongest evidence that the atoms of matter are built up of these two electrical units, namely the electron and the hydrogen nucleus or proton, as it is usually called when it forms part of the structure of any atom. It is probable that these two are the fundamental and indivisible units which build up our universe, but we may reserve in our mind the possibility that further inquiry may some day show that these units are complex, and divisible into even more fundamental entities. On the views we have outlined, the mass of the atom is the sum of the electrical masses of the individual charged units composing its structure, and there is no need to assume that any other kind of mass exists. At the same time, it is to be borne in mind that the actual mass of an atom may be somewhat less than the sum of the masses of component positive and negative electrons when in the free state. On account of the very close proximity of the charged units in the nucleus of an atom, and the consequent disturbance of the electric and magnetic fields surrounding them, such a decrease of mass is to be anticipated on general theoretical grounds.

We must now look back again to the earlier stages of the present epoch in order to trace the development of our ideas on the detailed structure of the atom. That electrons as such were important constituents was clear by 1900, but little real progress followed until the part played by the positive charges was made clear. New light was thrown on this subject by examining the deviation of α-particles when they passed through the atoms of matter. It was found that occasionally a swift α-particle was deflected from its rectilinear path through more than a right angle by an encounter with a single atom. In such a collision the laws of dynamics ordinarily apply, and the relation between the velocities of the colliding atoms before and after collision are exactly the same as if the two colliding particles are regarded as perfectly elastic spheres of minute dimensions. It must, however, be borne in mind that in these atomic collisions there is no question of mechanical impacts such as we observe with ordinary matter. The reaction between the two particles occurs through the intermediary of the powerful electric fields that surround them. Beautiful photographs illustrating the accuracy of these laws of collision between an α-particle and an atom have been obtained by Messrs. Wilson, Blackett, and others, while Mr. Wilson has recently obtained many striking illustrations of collisions between two electrons. Remembering the great kinetic energy of the α-particle, its deflexion through a large angle in a single atomic encounter shows clearly that very intense deflecting forces exist inside the atom. It seemed clear that electric fields of the required magnitude could be obtained only if the main charge of the atom were concentrated in a minute nucleus. From this arose the conception of the nuclear atom, now so well known, in which the heart of the atom is supposed to consist of a minute but massive nucleus, carrying a positive charge of electricity, and surrounded at a distance by the requisite number of electrons to form a neutral atom.

A detailed study of the scattering of α-particles at different angles, by Geiger and Marsden, showed that the results were in close accord with this theory, and that the intense electric forces near the nucleus varied according to the ordinary inverse square law. In addition, the experiments allowed us to fix an upper limit for the dimensions of the nucleus. For a heavy atom like that of gold the radius of the nucleus, if supposed to be spherical, was less than one-thousandth of the radius of the complete atom surrounded by its electrons, and certainly less than 4×10^{-12} cm. All the atoms were found to show this nuclear structure, and an approximate estimate was made of the nuclear charge of different atoms. This type of nuclear atom, based on direct experimental evidence, possesses some very simple properties. It is obvious that the number of units of resultant positive charge in the nucleus

fixes the number of the outer planetary electrons in the neutral atom. In addition, since these outer electrons are in some way held in equilibrium by the attractive forces from the nucleus, and, since we are confident from general physical and chemical evidence that all atoms of any one element are identical in their external structure, it is clear that their arrangement and motion must be governed entirely by the magnitude of the nuclear charge. Since the ordinary chemical and physical properties are to be ascribed mainly to the configuration and motion of the outer electrons, it follows that the properties of an atom are defined by a whole number representing its nuclear charge. It thus becomes of great importance to determine the value of this nuclear charge for the atoms of all the elements.

Data obtained from the scattering of α-particles, and also from the scattering of X-rays by light elements, indicated that the nuclear charge of an element was numerically equal to about half the atomic weight in terms of hydrogen. It was fairly clear from general evidence that the hydrogen nucleus had a charge one, and the helium nucleus (the α-particle) a charge two. At this stage another discovery of great importance provided a powerful method of attack on this problem. The investigation by Laue on the diffraction of X-rays by crystals had shown definitely that X-rays were electromagnetic waves of much shorter wavelength than light, and the experiments of Sir William Bragg and W. L. Bragg had provided simple methods for studying the spectra of a beam of X-rays. It was found that the spectrum in general shows a continuous background on which is superimposed a spectrum of bright lines. At this stage H. G. J. Moseley began a research with the intention of deciding whether the properties of an element depended on its nuclear charge rather than on its atomic weight as ordinarily supposed. For this purpose the X-ray spectra emitted by a number of elements were examined and found to be all similar in type. The frequency of a given line was found to vary very nearly as the square of a whole number which varied by unity in passing from one element to the next. Moseley identified this whole number with the atomic or ordinal number of the elements when arranged in increasing order of atomic weight, allowance being made for the known anomalies in the periodic table and for certain gaps corresponding to possible but missing elements. He concluded that the atomic number of an element was a measure of its nuclear charge, and the correctness of this deduction has been recently verified by Chadwick by direct experiments on the scattering of α-particles. Moseley's discovery is of fundamental importance, for it not only fixes the number of electrons in all the atoms, but also shows conclusively that the properties of an atom, as had been surmised, are determined not by its atomic weight but by its nuclear charge. A relation of unexpected simplicity is thus found to hold between the elements. No one could have anticipated that with few exceptions all atomic numbers between hydrogen 1, and uranium 92, would correspond to known elements. The great power of Moseley's law in fixing the atomic number of an element is well illustrated by the recent discovery by Coster and Hevesy in Copenhagen of the missing element of atomic number 72, which they have named "hafnium."

Once the salient features of the structure of atoms have been fixed and the number of electrons known, the further study of the structure of the atom falls naturally into two great divisions: one, the arrangement of the outer electrons which controls the main physical and chemical properties of an element, and the other, the structure of the nucleus on which the mass and radioactivity of the atom depend. On the nuclear theory the hydrogen atom is of extreme simplicity, consisting of a singly-charged positive nucleus with only one attendant electron. The position and motions of the single electron must account for the complicated optical spectrum, and whatever physical and chemical properties are to be attributed to the hydrogen atom. The first definite attack on the problem of the electronic structure of the atom was made by Niels Bohr. He saw clearly that, if this simple constitution was assumed, it is impossible to account for the spectrum of hydrogen on the classical electrical theories, but that a radical departure from existing views was necessary. For this purpose he applied to the atom the essential ideas of the quantum theory which had been developed by Planck for other purposes, and had been found of great service in explaining many fundamental difficulties in other branches of science. On Planck's theory, radiation is emitted in definite units or quanta, in which the energy E of a radiation is equal to $h\nu$ where ν is the frequency of the radiation measured by the ordinary methods and h a universal constant. This quantum of radiation is not a definite fixed unit like the atom of electricity, for its magnitude depends on the frequency of the radiation. For example, the energy of a quantum is small for visible light, but becomes large for radiation of high frequency corresponding to the X-rays or the γ-rays from radium.

Time does not allow me to discuss the underlying meaning of the quantum theory or the difficulties connected with it. Certain aspects of the difficulties were discussed in the presidential address before this Association by Sir Oliver Lodge at Birmingham in 1913. It suffices to say that this theory has proved of great value in several branches of science, and is supported by a large mass of direct experimental evidence.

In applying the quantum theory to the structure of the hydrogen atom Bohr supposed that the single electron could move in a number of stable orbits, controlled by the attractive force of the nucleus, without losing energy by radiation. The position and character of these orbits were defined by certain quantum relations depending on one or more whole numbers. It was assumed that radiation was only emitted when the electron for some reason was transferred from one stable orbit to another of lower energy. In such a case it was supposed that a homogeneous radiation was emitted of frequency ν determined by the quantum relation $E = h\nu$ where E was the difference of the energy of the electron in the two orbits. Some of these possible orbits are circular, others elliptical, with the nucleus as a focus, while if the change of mass of the electron with velocity is taken into account the orbits, as Sommerfeld showed, depend on two quantum numbers, and are not closed, but consist of a nearly elliptical orbit slowly rotating round the nucleus. In this way it is possible not only to account for the series relations between the bright lines of the hydrogen spectrum, but also to explain the

fine structure of the lines and the very complicated changes observed when the radiating atoms are exposed in a strong magnetic or electric field. Under ordinary conditions the electron in the hydrogen atom rotates in a circular orbit close to the nucleus, but if the atoms are excited by an electric discharge or other suitable method, the electron may be displaced and occupy any one of the stable positions specified by the theory. In a radiating gas giving the complete hydrogen spectrum there will be present many different kinds of hydrogen atoms, in each of which the electron describes one of the possible orbits specified by the theory. On this view it is seen that the variety of modes of vibration of the hydrogen atom is ascribed, not to complexity of the structure of the atom, but to the variety of stable orbits which an electron may occupy relative to the nucleus. This novel theory of the origin of spectra has been developed so as to apply not to hydrogen alone but to all the elements, and has been instrumental in throwing a flood of light on the relations and origin of their spectra, both X-ray and optical. The information thus gained has been applied by Bohr to determine the distribution of the electrons round the nucleus of any atom. The problem is obviously much less complicated for hydrogen than for a heavy atom, where each of the large number of electrons present acts on the other, and where the orbits described are much more intricate than the orbit of the single electron in hydrogen. Notwithstanding the great difficulties of such a complicated system of electrons in motion, it has been possible to fix the quantum numbers that characterise the motion of each electron, and to form at any rate a rough idea of the character of the orbit.

These planetary electrons divide themselves up into groups, according as their orbits are characterised by one or more equal quantum numbers. Without going into detail a few examples may be given to illustrate the conclusions which have been reached. As we have seen, the first element, hydrogen, has a nuclear charge of 1 and 1 electron; the second, helium, has a charge 2 and 2 electrons, moving in coupled orbits on the detailed nature of which there is still some uncertainty. These two electrons form a definite group, known as the K group, which is common to all the elements except hydrogen. For increasing nuclear charge the K group of electrons retains its characteristics, but moves with increasing speed, and approaches closer to the nucleus. As we pass from helium of atomic number 2 to neon, number 10, a new group of electrons is added consisting of two sub-groups, each of four electrons, together called the L group. This L group appears in all atoms of higher atomic number, and, as in the case of the K group, the speed of motion of the electrons increases, and the size of their orbits diminishes with the atomic number. When once the L group has been completed a new and still more complicated M group of electrons begins forming outside it, and a similar process goes on until uranium, which has the highest atomic number, is reached.

It may be of interest to try to visualise the conception of the atom we have so far reached by taking for illustration the heaviest atom, uranium. At the centre of the atom is a minute nucleus surrounded by a swirling group of 92 electrons, all in motion in definite orbits, and occupying but by no means filling a volume very large compared with that of the nucleus. Some of the electrons describe nearly circular orbits round the nucleus; others, orbits of a more elliptical shape with axes rotating rapidly round the nucleus. The motion of the electrons in the different groups is not necessarily confined to a definite region of the atom, but the electrons of one group may penetrate deeply into the region mainly occupied by another group, thus giving a type of inter-connexion or coupling between the various groups. The maximum speed of any electron depends on the closeness of the approach to the nucleus, but the outermost electron will have a minimum speed of more than 1000 kilometres per second, while the innermost K electrons have an average speed of more than 150,000 kilometres per second, or half the speed of light. When we visualise the extraordinary complexity of the electronic system we may be surprised that it has been possible to find any order in the apparent medley of motions.

In reaching these conclusions, which we owe largely to Prof. Bohr and his co-workers, every available kind of data about the different atoms has been taken into consideration. A study of the X-ray spectra, in particular, affords information of great value as to the arrangement of the various groups in the atom, while the optical spectrum and general chemical properties are of great importance in deciding the arrangements of the superficial electrons. While the solution of the grouping of the electrons proposed by Bohr has been assisted by considerations of this kind, it is not empirical in character, but has been largely based on general theoretical considerations of the orbits of electrons that are physically possible on the generalised quantum theory. The real problem involved may be illustrated in the following way. Suppose the gold nucleus be in some way stripped of its attendant seventy-nine electrons and that the atom is reconstituted by the successive addition of electrons one by one. According to Bohr, the atom will be reorganised in one way only, and one group after another will successively form and be filled up in the manner outlined. The nucleus atom has often been likened to a solar system where the sun corresponds to the nucleus and the planets to the electrons. The analogy, however, must not be pressed too far. Suppose, for example, we imagined that some large and swift celestial visitor traverses and escapes from our solar system without any catastrophe to itself or the planets. There will inevitably result permanent changes in the lengths of the month and year, and our system will never return to its original state. Contrast this with the effect of shooting an electron or α-particle through the electronic structure of the atom. The motion of many of the electrons will be disturbed by its passage, and in special cases an electron may be removed from its orbit and hurled out of its atomic system. In a short time another electron will fall into the vacant place from one of the outer groups, and this vacant place in turn will be filled up, and so on until the atom is again reorganised. In all cases the final state of the electronic system is the same as in the beginning. This illustration also serves to indicate the origin of the X-rays excited in the atom, for these arise in the process of re-formation of an atom from which an electron has been ejected, and the radiation

of highest frequency arises when the electron is removed from the K group.

It is possibly too soon to express a final opinion on the accuracy of this theory which defines the outer structure of the atom, but there can be no doubt that it constitutes a great advance. Not only does it offer a general explanation of the optical and X-ray spectra of the atom, but it accounts in detail for many of the most characteristic features of the periodic law of Mendeléeff. It gives us for the first time a clear idea of the reason for the appearance in the family of elements of groups of consecutive elements with similar chemical properties, such as the groups analogous to the iron group and the unique group of rare earths. The theory of Bohr, like all living theories, has not only correlated a multitude of isolated facts known about the atom, but has shown its power to predict new relations which can be verified by experiment. For example, the theory predicted the relations which must subsist between the Rydberg constants of the arc and spark spectra, and generally between all the successive optical spectra of an element, a prediction so strikingly confirmed by Paschen's work on the spectrum of doubly ionised aluminium and Fowler's work on the spectrum of trebly ionised silicon. Finally, it predicted with such great confidence the chemical properties of the missing element, number 72, that it gave the necessary incentive for its recent discovery.

While the progress of our knowledge of the outer structure of atoms has been much more rapid than could have been anticipated, we clearly see that only a beginning has been made on this great problem, and that an enormous amount of work is still required before we can hope to form anything like a complete picture even of the outer structure of the atom. We may be confident that the main features of the structure are clear, but in a problem of such great complexity progress in detail must of necessity be difficult and slow.

We have not so far referred to the very difficult question of the explanation on this theory of the chemical combination of atoms. In fact, as yet the theory has scarcely concerned itself with molecular structure. On the chemical side, however, certain advances have already been made, notably by G. N. Lewis, Kossel, and Langmuir, in the interpretation of the chemical evidence by the idea of shared electrons, which play a part in the electronic structure of two combined atoms. There can be little doubt that the next decade will see an intensified attack by physicists and chemists on this very important but undoubtedly very complicated question.

Before leaving this subject, it may be of interest to refer to certain points in Bohr's theory of a more philosophical nature. It is seen that the orbits and energies of the various groups of electrons can be specified by certain quantum numbers, and the nature of the radiation associated with a change of orbit can be defined. But at the same time we cannot explain why these orbits are alone permissible under normal conditions, or understand the mechanism by which radiation is emitted. It may be quite possible to formulate accurately the energy relation of the electrons in the atom on a simple theory, and to explain in considerable detail all the properties of an atom, without any clear understanding of the underlying processes which lead to these results. It is natural to hope that with advance of knowledge we may be able to grasp the details of the process which leads to the emission of radiation, and to understand why the orbits of the electrons in the atom are defined by the quantum relations. Some, however, are inclined to take the view that in the present state of knowledge it may be quite impossible in the nature of things to form that detailed picture in space and time of successive events that we have been accustomed to consider as so important a part of a complete theory. The atom is naturally the most fundamental structure presented to us. Its properties must explain the properties of all more complicated structures, including matter in bulk, but we may not, therefore, be justified in expecting that its processes can be explained in terms of concepts derived entirely from a study of molar properties. The atomic processes involved may be so fundamental that a complete understanding may be denied us. It is early yet to be pessimistic on this question, for we may hope that our difficulties may any day be resolved by further discoveries.

We must now turn our attention to that new and comparatively unexplored territory, the nucleus of the atom. In a discussion on the structure of the atom ten years ago, in answer to a question on the structure of the nucleus, I was rash enough to say that it was a problem that might well be left to the next generation, for at that time there seemed to be few obvious methods of attack to throw light on its constitution. While much more progress has been made than appeared possible at that time, the problem of the structure of the nucleus is inherently more difficult than the allied problem already considered of the structure of the outer atom, where we have a wealth of information obtained from the study of light and X-ray spectra and from the chemical properties to test the accuracy of our theories.

In the case of the nucleus, we know its resultant charge, fixed by Moseley's law, and its mass, which is very nearly equal to the mass of the whole atom, since the mass of the planetary electrons is relatively very small and may for most purposes be neglected. We know that the nucleus is of size minute compared with that of the whole atom, and can with some confidence set a maximum limit to its size. The study of radioactive bodies has provided us with very valuable information on the structure of the nucleus, for we know that the α- and β-particles must be expelled from it, and there is strong evidence that the very penetrating γ-rays represent modes of vibration of the electrons contained in its structure. In the long series of transformations which occur in the uranium atom, eight α-particles are emitted and six electrons, and it seems clear that the nucleus of a heavy atom is built up, in part at least, of helium nuclei and electrons. It is natural to suppose that many of the ordinary stable atoms are constituted in a similar way. It is a matter of remark that no indication has been obtained that the lightest nucleus, namely, that of hydrogen, is liberated in these transformations, where the processes occurring are of so fundamental a character. At the same time, it is evident that the hydrogen nucleus must be a unit in the structure of some atoms,

and this has been confirmed by direct experiment. Dr. Chadwick and I have observed that swift hydrogen nuclei are released from the elements boron, nitrogen, fluorine, sodium, aluminium, and phosphorus when they are bombarded by swift α-particles, and there is little room for doubt that these hydrogen nuclei form an essential part of the nuclear structure. The speed of ejection of these nuclei depends on the velocity of the α-particle and on the element bombarded. It is of interest to note that the hydrogen nuclei are liberated in all directions, but the speed in the backward direction is always somewhat less than in the direction of the α-particle. Such a result receives a simple explanation if we suppose that the hydrogen nuclei are not built into the main nucleus but exist as satellites probably in motion round a central core. There can be no doubt that bombardment by α-particles has effected a veritable disintegration of the nuclei of this group of elements. It is significant that the liberation of hydrogen nuclei only occurs in elements of odd atomic number, namely, 5, 7, 9, 11, 13, 15, the elements of even number appearing quite unaffected. For a collision of an α-particle to be effective, it must either pass close to the nucleus or actually penetrate its structure. The chance of this is excessively small on account of the minute size of the nucleus. For example, although each individual α-particle will pass through the outer structure of more than 100,000 atoms of aluminium in its path, it is only about one α-particle in a million that gets close enough to the nucleus to effect the liberation of its hydrogen satellite.

This artificial disintegration of elements by α-particles takes place only on a minute scale, and its observation has only been possible by the counting of individual swift hydrogen nuclei by the scintillations they produce in zinc sulphide.

These experiments suggest that the hydrogen nucleus or proton must be one of the fundamental units which build up a nucleus, and it seems highly probable that the helium nucleus is a secondary building unit composed of the very close union of four protons and two electrons. The view that the nuclei of all atoms are ultimately built up of protons of mass nearly one and of electrons has been strongly supported and extended by the study of isotopes. It was early observed that some of the radioactive elements which showed distinct radioactive properties were chemically so alike that it was impossible to effect their separation when mixed together. Similar elements of this kind were called "isotopes" by Soddy, since they appeared to occupy the same place in the periodic table. For example, a number of radioactive elements in the uranium and thorium series have been found to have physical and chemical properties identical with those of ordinary lead, but yet to have atomic weights differing from ordinary lead, and also distinctive radioactive properties. The nuclear theory of the atom offers at once a simple interpretation of the relation between isotopic elements. Since the chemical properties of an element are controlled by its nuclear charge and little influenced by its mass, isotopes must correspond to atoms with the same nuclear charge but of different nuclear mass. Such a view also offers a simple explanation why the radioactive isotopes show different radioactive properties, for it is to be anticipated that the stability of a nucleus will be much influenced by its mass and arrangement.

Our knowledge of isotopes has been widely extended in the last few years by Aston, who has devised an accurate direct method for showing the presence of isotopes in the ordinary elements. He has found that some of the elements are "pure"—*i.e.* consist of atoms of identical mass—while others contain a mixture of two or more isotopes. In the case of the isotopic elements, the atomic mass, as ordinarily measured by the chemist, is a mean value depending on the atomic masses of the individual isotopes and their relative abundance. These investigations have not only shown clearly that the number of distinct species of atoms is much greater than was supposed, but have also brought out a relation between the elements of great interest and importance. The atomic masses of the isotopes of most of the elements examined have been found, to an accuracy of about one in a thousand, to be whole numbers in terms of oxygen, 16. This indicates that the nuclei are ultimately built up of protons of mass very nearly 1 and of electrons. It is natural to suppose that this building unit is the hydrogen nucleus, but that its average mass in the complex nucleus is somewhat less than its mass in the free state owing to the close packing of the charged units in the nuclear structure. We have already seen that the helium nucleus of mass 4 is probably a secondary unit of great importance in the building up of many atoms, and it may be that other simple combinations of protons and electrons of mass 2 and 3 occur in the nucleus, but these have not been observed in the free state.

While the mass of the majority of the isotopes are nearly whole numbers, certain cases have been observed by Aston where this rule is slightly departed from. Such variations in mass may ultimately prove of great importance in throwing light on the arrangement and closeness of packing of the protons and electrons, and for this reason it is to be hoped that it may soon prove possible to compare atomic masses of the elements with much greater precision even than at present.

While we may be confident that the proton and the electron are the ultimate units which take part in the building up of all nuclei, and can deduce with some certainty the number of protons and electrons in the nuclei of all atoms, we have little, if any, information on the distribution of these units in the atom or on the nature of the forces that hold them in equilibrium. While it is known that the law of the inverse square holds for the electrical forces some distance from the nucleus, it seems certain that this law breaks down inside the nucleus. A detailed study of the collisions between α-particles and hydrogen atoms, where the nuclei approach very close to each other, shows that the forces between nuclei increase ultimately much more rapidly than is to be expected from the law of the inverse square, and it may be that new and unexpected forces may come into importance at the very small distances separating the protons and electrons in the nucleus. Until we gain more information on the nature and law of variation of the forces inside the nucleus, further progress on the detailed structure of the nucleus may be difficult. At the same time, there

are still a number of hopeful directions in which an attack may be made on this most difficult of problems. A detailed study of the γ-rays from radioactive bodies may be expected to yield information as to the motion of the electrons inside the nucleus, and it may be, as Ellis has suggested, that quantum laws are operative inside as well as outside the nucleus. From a study of the relative proportions of the elements in the earth's crust, Harkins has shown that elements of even atomic number are much more abundant than elements of odd number, suggesting a marked difference of stability in these two classes of elements. It seems probable that any process of stellar evolution must be intimately connected with the building up of complex nuclei from simpler ones, and its study may thus be expected to throw much light on the evolution of the elements.

The nucleus of a heavy atom is undoubtedly a very complicated system, and in a sense a world of its own, little, if at all, influenced by the ordinary physical and chemical agencies at our command. When we consider the mass of a nucleus compared with its volume it seems certain that its density is many billions of times that of our heaviest element. Yet, if we could form a magnified picture of the nucleus, we should expect that it would show a discontinuous structure, occupied but not filled by the minute building units, the protons and electrons, in ceaseless rapid motion controlled by their mutual forces.

Before leaving this subject it is desirable to say a few words on the important question of the energy relations involved in the formation and disintegration of atomic nuclei, first opened up by the study of radioactivity. For example, it is well known that the total evolution of energy during the complete disintegration of one gram of radium is many millions of times greater than in the complete combustion of an equal weight of coal. It is known that this energy is initially mostly emitted in the kinetic form of swift α- and β-particles, and the energy of motion of these bodies is ultimately converted into heat when they are stopped by matter. Since it is believed that the radioactive elements are analogous in structure to the ordinary inactive elements, the idea naturally arose that the atoms of all the elements contained a similar concentration of energy, which would be available for use if only some simple method could be discovered of promoting and controlling their disintegration. This possibility of obtaining new and cheap sources of energy for practical purposes was naturally an alluring prospect to the lay and scientific man alike. It is quite true that, if we were able to hasten the radioactive processes in uranium and thorium so that the whole cycle of their disintegration could be confined to a few days instead of being spread over thousands of millions of years, these elements would provide very convenient sources of energy on a sufficient scale to be of considerable practical importance. Unfortunately, although many experiments have been tried, there is no evidence that the rate of disintegration of these elements can be altered in the slightest degree by the most powerful laboratory agencies. With increase in our knowledge of atomic structure there has been a gradual change of our point of view on this important question, and there is by no means the same certainty to-day as a decade ago that the atoms of an element contain hidden stores of energy. It may be worth while to spend a few minutes in discussing the reason for this change in outlook. This can best be illustrated by considering an interesting analogy between the transformation of a radioactive nucleus and the changes in the electron arrangement of an ordinary atom. It is now well known that it is possible by means of electron bombardment or by appropriate radiation to excite an atom in such a way that one of its superficial electrons is displaced from its ordinary stable position to another temporarily stable position further removed from the nucleus. This electron in course of time falls back into its old position, and its potential energy is converted into radiation in the process. There is some reason for believing that the electron has a definite average life in the displaced position, and that the chance of its return to its original position is governed by the laws of probability. In some respects an "excited" atom of this kind is thus analogous to a radioactive atom, but of course the energy released in the disintegration of a nucleus is of an entirely different order of magnitude from the energy released by return of the electron in the excited atom. It may be that the elements, uranium and thorium, represent the sole survivals in the earth to-day of types of elements that were common in the long-distant ages, when the atoms now composing the earth were in course of formation. A fraction of the atoms of uranium and thorium formed at that time has survived over the long interval on account of their very slow rate of transformation. It is thus possible to regard these atoms as having not yet completed the cycle of changes which the ordinary atoms have long since passed through, and that the atoms are still in the "excited" state where the nuclear units have not yet arranged themselves in positions of ultimate equilibrium, but still have a surplus of energy which can only be released in the form of the characteristic radiation from active matter. On such a view, the presence of a store of energy ready for release is not a property of all atoms, but only of a special class of atoms like the radioactive atoms which have not yet reached the final state for equilibrium.

It may be urged that the artificial disintegration of certain elements by bombardment with swift α-particles gives definite evidence of a store of energy in some of the ordinary elements, for it is known that a few of the hydrogen nuclei, released from aluminium for example, are expelled with such swiftness that the particle has a greater individual energy than the α-particle which causes their liberation. Unfortunately, it is very difficult to give a definite answer on this point until we know more of the details of this disintegration.

On the other hand, another method of attack on this question has become important during the last few years, based on the comparison of the relative masses of the elements. This new point of view can best be illustrated by a comparison of the atomic masses of hydrogen and helium. As we have seen, it seems very probable that helium is not an ultimate unit in the structure of nuclei, but is a very close combination of four hydrogen nuclei and two electrons. The mass of the helium nucleus, 4·00 in terms of $O=16$, is considerably less than the mass, 4·03, of four hydrogen nuclei. On modern views there is believed to be a very

close connexion between mass and energy, and this loss in mass in the synthesis of the helium nucleus from hydrogen nuclei indicates that a large amount of energy in the form of radiation has been released in the building of the helium nucleus from its components. It is easy to calculate from this loss of mass that the energy set free in forming one gram of helium is large even compared with that liberated in the total disintegration of one gram of radium. For example, calculation shows that the energy released in the formation of one pound of helium gas is equivalent to the energy emitted in the complete combustion of about eight thousand tons of pure carbon. It has been suggested by Eddington and Perrin that it is mainly to this source of energy that we must look to maintain the heat emission of the sun and hot stars over long periods of time. Calculations of the loss of heat from the sun show that this synthesis of helium need only take place slowly in order to maintain the present rate of radiation for periods of the order of one thousand million years. It must be acknowledged that these arguments are somewhat speculative in character, for no certain experimental evidence has yet been obtained that helium can be formed from hydrogen.

The evidence of the slow rate of stellar evolution, however, certainly indicates that the synthesis of helium, and perhaps other elements of higher atomic weight, may take place slowly in the interior of hot stars. While in the electric discharge through hydrogen at low pressure we can easily reproduce the conditions of the interior of the hottest star so far as regards the energy of motion of the electrons and hydrogen nuclei, we cannot hope to reproduce that enormous density of radiation which must exist in the interior of a giant star. For this and other reasons it may be very difficult, or even impossible, to produce helium from hydrogen under laboratory conditions.

If this view of the great heat emission in the formation of helium be correct, it is clear that the helium nucleus is the most stable of all nuclei, for an amount of energy corresponding to three or four α-particles would be required to disrupt it into its components. In addition, since the mass of the proton in nuclei is nearly 1·000 instead of its mass 1·0072 in the free state, it follows that much more energy must be put into the atom than will be liberated by its disintegration into its ultimate units. At the same time, if we consider an atom of oxygen, which may be supposed to be built up of four helium nuclei as secondary units, the change of mass, if any, in its synthesis from already formed helium nuclei is so small that we cannot yet be certain whether there will be a gain or loss of energy by its disintegration into helium nuclei, but in any case we are certain that the magnitude of the energy will be much less than for the synthesis of helium from hydrogen. Our information on this subject of energy changes in the formation or disintegration of atoms in general is as yet too uncertain and speculative to give any decided opinion on future possibilities in this direction, but I have endeavoured to outline some of the main arguments which should be taken into account.

I must now bring to an end my survey, I am afraid all too brief and inadequate, of this great period of advance in physical science. In the short time at my disposal it has been impossible for me, even if I had the knowledge, to refer to the great advances made during the period under consideration in all branches of pure and applied science. I am well aware that in some departments the progress made may justly compare with that of my own subject. In these great additions to our knowledge of the structure of matter every civilised nation has taken an active part, but we may be justly proud that Great Britain has made many fundamental contributions. With this country I must properly include the Dominions overseas, for they have not been behindhand in their contributions to this new knowledge. It is, I am sure, a matter of pride to this country that the scientific men of the Dominions have been responsible for some of the most fundamental discoveries of this epoch, particularly in radioactivity.

This tide of advance was continuous from 1896, but there was an inevitable slackening during the War. It is a matter of good omen that, in the last few years, the old rate of progress has not only been maintained but even intensified, and there appears to be no obvious sign that this period of great advances has come to an end. There has never been a time when the enthusiasm of the scientific workers was greater, or when there was a more hopeful feeling that great advances were imminent. This feeling is no doubt in part due to the great improvement during this epoch of the technical methods of attack, for problems that at one time seemed unattackable are now seen to be likely to fall before the new methods. In the main, the epoch under consideration has been an age of experiment, where the experimenter has been the pioneer in the attack on new problems. At the same time, it has been also an age of bold ideas in theory, as the quantum theory and the theory of relativity so well illustrate.

I feel it is a great privilege to have witnessed this period, which may almost be termed the renaissance of physics. It has been of extraordinary intellectual interest to watch the gradual unfolding of new ideas and the ever-changing methods of attack on difficult problems. It has been of great interest, too, to note the comparative simplicity of the ideas that have ultimately emerged. For example, no one could have anticipated that the general relation between the elements would prove to be of so simple a character as we now believe it to be. It is an illustration of the fact that Nature appears to work in a simple way, and that the more fundamental the problem, often the simpler are the conceptions needed for its explanation. The rapidity and certitude of the advance in this epoch have largely depended on the fact that it has been possible to devise experiments so that few variables were involved. For example, the study of the structure of the atom has been much facilitated by the possibility of examining the effects due to a single atom of matter, or, as in radioactivity or X-rays, of studying processes going on in the individual atom which were quite uninfluenced by external conditions.

In watching the rapidity of this tide of advance in physics I have become more and more impressed by the power of the scientific method of extending our knowledge of Nature. Experiment, directed by the disciplined imagination either of an individual, or still better, of a group of individuals of varied mental

outlook, is able to achieve results which far transcend the imagination alone of the greatest natural philosopher. Experiment without imagination, or imagination without recourse to experiment, can accomplish little, but, for effective progress, a happy blend of these two powers is necessary. The unknown appears as a dense mist before the eyes of men. In penetrating this obscurity we cannot invoke the aid of supermen, but must depend on the combined efforts of a number of adequately trained ordinary men of scientific imagination. Each in his own special field of inquiry is enabled by the scientific method to penetrate a short distance, and his work reacts upon and influences the whole body of other workers. From time to time there arises an illuminating conception, based on accumulated knowledge, which lights up a large region and shows the connexion between these individual efforts so that a general advance follows. The attack begins anew on a wider front, and often with improved technical weapons. The conception which led to this advance often appears simple and obvious when once it has been put forward. This is a common experience, and the scientific man often feels a sense of disappointment that he himself had not foreseen a development which ultimately seems so clear and inevitable.

The intellectual interest due to the rapid growth of science to-day cannot fail to act as a stimulus to young men to join in scientific investigation. In every branch of science there are numerous problems of fundamental interest and importance which await solution. We may confidently predict an accelerated rate of progress of scientific discovery, beneficial to mankind certainly in a material, but possibly even more so in an intellectual sense. In order to obtain the best results, certain conditions must, however, be fulfilled. It is necessary that our universities and other specific institutions should be liberally supported, so as not only to be in a position to train adequately young investigators of promise, but also to serve themselves as active centres of research. At the same time there must be a reasonable competence for those who have shown a capacity for original investigation. Not least, peace throughout the civilised world is as important for rapid scientific development as for general commercial prosperity. Indeed, science is truly international, and for progress in many directions the co-operation of nations is as essential as the co-operation of individuals. Science, no less than industry, desires a stability not yet achieved in world conditions.

There is an error far too prevalent to-day that science progresses by the demolition of former well-established theories. Such is very rarely the case. For example, it is often stated that Einstein's general theory of relativity has overthrown the work of Newton on gravitation. No statement could be further from the truth. Their works, in fact, are scarcely comparable, for they deal with different fields of thought. So far as the work of Einstein is relevant to that of Newton, it is simply a generalisation and broadening of its basis; in fact, a typical case of mathematical and physical development. In general, a great principle is not discarded, but so modified that it rests on a broader and more stable basis.

It is clear that the splendid period of scientific activity which we have here reviewed owes much of its success and intellectual appeal to the labours of those great men in the past, who wisely laid the sure foundations on which the scientific worker builds to-day, or to quote from the words inscribed in the dome of the National Gallery, "The works of those who have stood the test of ages have a claim to that respect and veneration to which no modern can pretend."

Scientific Problems and Progress.[1]

SUMMARIES OF ADDRESSES OF PRESIDENTS OF SECTIONS OF THE BRITISH ASSOCIATION.

THE ORIGIN OF SPECTRA.

THE focus of Prof. McLennan's remarks in his presidential address to Section A (Mathematics and Physics), to be delivered on September 17, is Bohr's theory of the origin of radiation and of atomic structure. Evidence in support of the theory is drawn largely from recent researches on the spectra of the elements.

Among the subjects discussed are the significance of the fine structure of the spectral lines of hydrogen and the recent attempts to devise a model of the helium atom capable of accounting for the characteristics of the helium spectrum.

In dealing with the question of the genesis of atoms of various types, illustrations are given of the view recently put forward by Bohr that the fundamental process that must apply consists in the successive binding of electrons by a nucleus originally naked. Bohr's scheme of electronic orbits for the atoms of different elements provides a means of establishing a connexion between spectral series formulæ of different types and the energy levels in atoms and, also, of deducing the values of resonance and ionisation potentials, hitherto undetermined, for a number of elements. Special attention is paid to the elements of the lead-tin and chromium-manganese groups.

A number of illustrations are given of the Kossel-Sommerfeld Displacement Law, and the importance of the recent work of Fowler and of Paschen in this connexion is emphasised. Spectroscopic data, recently obtained, that are likely to lead to extensions of this work are also discussed.

In dealing with the magnetic properties of certain contiguous elements, anomalies are referred to that apparently do not find so ready an explanation with Bohr's scheme of electronic orbits for the atoms of successive elements as the Kossel-Sommerfeld Displacement Law. Reference is also made to the principle of quantisation in space recently brought into prominence by the interesting experiments of Gerlach and Stern and by the work of R. W. Wood and Ellett.

[1] All the presidential addresses are published in full in "The Advancement of Science: 1923" (London: John Murray).

This latter, it will be recalled, deals with the power possessed by weak magnetic fields of modifying the capability shown by the vapours of mercury and sodium of polarising radiation scattered by them.

The adiabatic hypothesis enunciated by Ehrenfest is discussed, and also the use of this principle in conjunction with the quantum theory in elucidating Zeeman effects of the normal type. Reference is made, as well, to the interesting and suggestive attempts of Heisenberg and Sommerfeld to find in a development of the quantum theory an explanation of the anomalous Zeeman effect exhibited by certain classes of spectral lines. In this application of the quantum theory it is assumed that the doublet separations characteristic of series such as those of the arc spectra of the alkali elements are in reality Zeeman separations produced by intra-atomic magnetic fields. In conclusion there are illustrations of the magnitude of such intra-atomic magnetic fields, and a discussion of some of the difficulties raised by Heisenberg and Sommerfeld's theory and of some objections in the way of its immediate and general acceptance.

Physical Chemistry of Surfaces.

The subjects dealt with by Prof. F. G. Donnan, in his address to Section B (Chemistry) are principally molecular orientation and molecular dimensions at surfaces and in surface films, molecular concentration at surfaces and its effect on surface tension, electrical potential differences at surfaces, stabilities of foams, oil suspensions, lyophobic hydrosols, and oil emulsions. The surfaces especially considered are the liquid-gas and liquid-liquid surfaces. The researches of W. B. Hardy have led to the conception of surface layers of oriented molecules, as the result of unsymmetrical fields of force surrounding molecules, due to the presence of active atoms or atomic groups. The views of Hardy have been confirmed by the work of W. D. Harkins and his collaborators.

The study of *unimolecular* surface layers of insoluble substances on the surface of water, initiated by the late Lord Rayleigh and developed by H. Devaux and A. Marcelin, has led in the hands of I. Langmuir and N. K. Adam to the determination of molecular and atomic dimensions. Certain recent investigations by X-ray methods have an interesting bearing on these results.

Unimolecular layers may also be formed by the adsorption of vapours on liquid and solid surfaces. Dissolved substances which lower the surface tension of a gas-liquid or liquid-liquid interface concentrate at these interfaces. Do they form unimolecular layers?

Electric potential differences exist at the gas-liquid, liquid-liquid, and solid-liquid interfaces. These potential differences are affected by "surface-active" substances, by ions, colloidal micelles, etc. The potential differences determine the stabilities of oil suspensions and lyophobic hydrosols. The "critical" potential differences and the "critical zone" of potential difference are of importance in such cases.

The formation of concentrated surface layers and surface films plays an important rôle in the production and stabilisation of emulsions. Surface actions are of importance in biological phenomena. The existence and activity of the living organism are dynamic and depend on an environment which is not in equilibrium. The living organism is an *individual*. Further progress will depend on the study of the particular actions of individuals rather than the average behaviour of "crowds."

Evolutional Palæontology.

The presidential address by Dr. Gertrude Elles to Section C (Geology) is on the subject of "Evolutional Palæontology in Relation to the Lower Palæozoic Rocks." The problems of the Lower Palæozoic Rocks still awaiting solution are in the main those of classification and structure, which are largely interdependent. The most satisfactory solution appears to lie in the application of the principles of evolutional palæontology. The most effective modern classification of strata is that based upon the coming in of new forms of life, but if it is to be of wide application this must not be connected directly with changes in the character of the sedimentation.

The variation in the nature of shallow-water faunas due to various factors such as temperature, salinity, and clearness of the water, is illustrated by reference to the recent work at the Danish Biological Station; the classification and correlation of such deposits must be a matter of great difficulty unless a common principle can be introduced. The standard for purposes of classification must be sought in the faunas of the deeper waters of the Lower Palæozoic seas, where the changes in the fauna show primarily as an advance in the evolutional stage of the organisms concerned. The various shallow-water deposits should be referred to those of deeper-water origin when possible, or the relative ages may to some extent be determined by noting the evolutional stage reached by various organisms composing the faunas.

These principles are illustrated by a study of the evolution of the Graptoloidea as the characteristic fauna of the deeper-water sediments of the Lower Palæozoic, and it is shown that important evolutional stages are characteristic of definite geological horizons, these being recognisable without any knowledge of the various Graptolite species. In the faunas of the shallower-waters the evolution of certain features in some species-groups of the Trilobita are described and the horizons at which these occur are noted. Mention is made of the work already published on other fossil phyla, and attention is especially directed to that of various observers on the evolution of the corals in the Carboniferous as the type of work to be aimed at in the future in the Lower Palæozoic Rocks.

The old purely descriptive work so often carried out entirely in the museum or laboratory must give place to that in which fossils are regarded as parts of once-living entities possessing definite ancestors and descendants developing along definite lines, the relationships of these being controlled always by field work.

Zoology and its Human Aspects.

Prof. Ashworth devoted the first part of his address to Section D (Zoology), on September 13, to a brief retrospective glance over some of the lines of development in zoology since the last meeting in

Liverpool. He referred to the rapid extension of physiological methods of inquiry to the lower organisms, the discovery of artificial parthenogenesis, the intensive study of egg-cleavage, cell-lineage, and the maturation of the egg and sperm, the remarkable progress of cytology, and to researches on the structural basis of heredity and on the nuclear mechanism correlated with sex. Other subjects discussed were the study of the finer structure of the nerve-cell and its processes and of the neuromotor system of the Protozoa, the investigations on the ciliate Protozoa, especially on Paramæcium, with the purpose of ascertaining whether decline and death depend on inherent factors or on external conditions, and the researches on the culture of tissues, which are leading to a knowledge of the conditions which determine the growth and differentiation of somatic cells.

In the second part of the address some of the bearings of zoology on human welfare were considered. At the time of the last meeting in Liverpool insects were suspected of acting as transmitters of certain pathogenic organisms to man, but these cases were few and in no single instance had the life-cycle of the organism been worked out and the mode of transmission from insect to man ascertained. The part played by the mosquito as host and transmitter of the parasite of malaria was made known by Ross nearly two years after that meeting. Of the ten important examples of arthropods now proved to act as carriers of pathogenic organisms to man, Prof. Ashworth chose three for consideration, namely, Stegomyia and yellow fever, tsetse-flies and sleeping-sickness, and the flea *Xenopsylla cheopis* and plague, this last providing a fine illustration of the value of careful work on the systematics and on the structure and bionomics of the insect concerned. Intensive work on the Protozoa has been an outstanding feature during the last twenty-five years, and *Entamœba histolytica*, the organism of amœbic dysentery, was taken as an example of the importance of researches on Protozoa which directly affect man. Of the notable investigations on parasitic worms, reference was made to the great advances in our knowledge of the life-history and bionomics of Ancylostoma and of Schistosoma (Bilharzia), which have enabled effective measures to be taken against infection by these parasites.

In conclusion, Prof. Ashworth referred to the place and value of zoology in the medical curriculum, gave an outline of the subjects which he considered should be included in the course of zoology for medical students, and invited discussion on this part of the address.

The British Empire as a Maritime State.

The subject of Dr. Vaughan Cornish's presidential address to Section E (Geography) is the "Geographical Position of the British Empire." It may be thought that an Empire on which the sun never sets, with lands in both hemispheres and on every continent, cannot be assigned a place upon the map, and in fact so long as it is regarded from the continental point of view it cannot be given a definite geographical position. It is, however, a maritime State, the metropolitan and other provinces being united by ocean routes on which lie British ports of call which can be used as naval stations, but separated strategically by those parts of the ocean which are not so provided, and are readily dominated from the ports of other Great Powers. An examination of these conditions shows that, taking account only of the communications which are available in all circumstances, the lands of the British Empire are connected by the Atlantic and Indian, separated by the North Pacific Ocean. Hence the geographical position of the Empire is well represented by the form of Mercator map in which the meridian of Greenwich is central and the right- and left-hand edges are at longitude 180°. The Empire thus appears astride the North Atlantic and the Indian Ocean, but with its Pacific shores unconnected.

A symmetrical arrangement is revealed upon this map if a direct line (part of a great circle) be drawn from Halifax, Nova Scotia, the eastern terminal of the Canadian Pacific Railway, to Fremantle, the western terminal port of the Australian railways. This direct line (twisted on the map into the form of the letter S) passes through Lower Egypt close to the Suez Canal, which is not very far from its middle point. It follows somewhat closely the main steamship track of the Empire. At one end is Canada, at the other Australasia, the British Isles on the north and South Africa on the south. The coloured populations of the Empire are also distributed symmetrically with reference to the line, those of India on the east, of Africa on the west, so that the great circle from Halifax, N.S., eastwards to Fremantle is the geometrical axis of the Empire.

The Empire as thus mapped can be shown to have an intermediate position on the present commercial and international communications of the world such as no other Great Power occupies, so that the British, in a greater degree than any other people, are the doorkeepers of the world.

The consolidation of the position turns on the future of colonisation during the time which remains before the untilled lands of the world are occupied by peasantry. In the second part of the address the present tendency of this movement is traced both among coloured and white peoples, and special attention is given to the question, now so much debated, whether a surplus of birth-rate over death-rate in Great Britain is, or is not, in the interests of the country, of the peoples of the Empire, and of mankind.

Population and Unemployment.

The common impression that Europe is already threatened with over-population may be traced to two sources—to observation of the exceptional volume of unemployment to-day, and to the words of certain economists describing Europe before the War. Sir William Beveridge deals with these subjects in his presidential address to be given to Section F (Economics) on Monday, September 17. Unemployment does not necessarily or naturally point to excessive growth of population; severe and prolonged unemployment has occurred at times and in countries which were certainly not marked by over-population. Statements such as those of Mr. Keynes, that Europe was over-populated even before the War, appear ill-founded; in Europe, no less than in the New World, the yield of corn

per acre and per head of the population was rising, not falling; the price of corn relatively to other commodities was falling, not rising, up to the eve of War. There is still room for the expansion of the white races. In Britain, as distinct from Europe as a whole, the rate of material progress which marked the Victorian age was not maintained from 1900 to 1910; this apparent check, however, may have been temporary and due to special causes.

In considering the position of Britain after the War, the example of German Austria, a highly specialised and advanced community depending on free trade over a large and varied area, is apposite. The optimum density of population in any given region depends, not on that region alone, but also on the economic conditions and needs of the rest of the world. A decline of international dealing hurts all, but most of all the highly specialised communities typified by German Austria and Britain. The suggestion that we should avoid the "Austrian risk" in future by aiming at self-sufficiency is not practical. Britain, as we know it, and with anything like its present population, depends upon peace and trade. Its excessive unemployment to-day can be fully explained by the War and its aftermath of economic disorganisation, and the remedy must be sought elsewhere than in birth control.

Though, however, increased birth control is not required by the conditions of Europe before the War and is irrelevant to its present troubles, the problem of numbers has to be faced. Man cannot with safety indefinitely reduce the death-rate and leave the birth-rate to look after itself; as a matter of history, he has at almost all stages of his development limited the number of his descendants. The problem of population is, at the moment, a matter for suspension of judgment and inquiry. Two inquiries in particular are suggested: one, into the potential agricultural resources of the world, analogous to the inquiries made at various times as to coal; the other, into the physical, psychological, and social effects of the restriction of fertility which has become general among European races in the past fifty years.

Transport and its Debt to Science.

Sir Henry Fowler's address to Section G (Engineering) deals with the subject of transport and its indebtedness to science. Since its foundation the city of Liverpool has been associated with transport, and no town owes so much to the facilities to trade which transport has afforded, or has played so frequently the part of a pioneer in the inception of new methods. The Mersey and Trent Canal, the Manchester Ship Canal, the Rainhill Railway trials, the electrification of the Liverpool and Southport railway, and the Commercial Motor Trials of the Liverpool Self-Propelled Traffic Association testify to this.

All advances in methods of transport have been the result of the availability of scientific knowledge. Since the time of Watt these advances have taken place when the "ordered knowledge of natural phenomena" has allowed. Progress has depended upon this knowledge; locomotive design benefited by the experiments of Schmidt; electric traction by the numberless researches into electrical phenomena, and the development of the turbine by Parsons: the work of the latter gave a fresh impulse to marine transport. The motor car and the aeroplane owe much to the Otto cycle and the work of Daimler on internal combustion engines. The above are the results of work on methods of propulsion. The advance in our knowledge of material has also played its part. Until the invention of Bessemer the material requisite was not available in quantities sufficient to allow of much progress being made. The early work of Hadfield on alloy steels has developed in such a manner that the motor car and the aeroplane are possible as we have them to-day. It is not alone in general and large questions that scientific knowledge has helped transport, but it can be shown that a careful investigation of the properties of the steel from which locomotive crank axles are made has led to a large increase in their life.

One great trouble with scientific development on industrial lines is the difficulty of obtaining correct results from practical application. The transport bodies have no axe to grind in the use of any particular thing, and should show their appreciation of their indebtedness to science by freely giving the results of their work.

Another trouble which still exists is that the personal contact of the scientific man and the practical engineer does not occur frequently enough, and the meetings of the Association should be more freely used for this purpose.

Egypt as a Field for Anthropological Research.

As the habits, modes of life, and occupations of all communities are immediately dependent upon the features and products of the land in which they dwell, any inquiry into Egyptian origins ought to begin with the question, What were the physical conditions which prevailed in Egypt and its bordering deserts in the period immediately preceding, and during the rise of, the Egyptian civilisation? Discussing what is actually known about the fauna and flora of the dynastic and predynastic periods, Prof. Newberry, in his presidential address to be delivered to Section H (Anthropology) on September 17, shows that a material change must have taken place in the character of the climate of North-Eastern Africa since pre-agricultural days. The fauna and flora have receded southwards, and the physical conditions which now prevail in the region north of the Atbara are similar to those which prevailed in the deserts on either side of the Lower Nile Valley in early times. The people living in this part of the Anglo-Egyptian Sudan are Hamite, and, as Prof. Seligman has shown, the least modified of these people are physically identical with the predynastic Egyptians of Upper Egypt. Prof. Newberry suggests that they, like the fauna and flora, have receded southwards under the pressure of the advance of civilisation, and that the physical conditions of the country have preserved them to a great extent in their primitive life and pursuits. The picture of life in the Taka country as drawn by Burckhardt in 1813 would, except in some unimportant details, equally well depict the predynastic Egyptians.

Prof. Newberry proceeds to show that the earliest

civilisation in Egypt arose in the Delta, and that it spread up the river. Before Menes conquered the north there had been a kingdom of Middle and Upper Egypt, and before that a kingdom with its capital at Sais in the North-Western Delta. The people of the North-Western Delta were closely connected with the early Cretans, and were of the same race as the pre-dynastic people of Upper Egypt. In the Eastern Delta at an early period lived a pastoral clan that had come in from Western Asia and brought into Egypt the domesticated goat and sheep, as well as two important cults connected with trees that were not indigenous to the soil of Egypt. The absence of timber trees makes it doubtful whether the art of the carpenter arose in the Nile Valley. Architectural styles founded on wood construction cannot well have originated in a timberless country, nor could the art of building sailing or sea-going ships. It may be doubted that the custom of burying the dead in wooden coffins arose in Egypt; the resins used in embalming were not native to the Nile Valley. No incense trees or shrubs are known in Egypt, hence it is probable that the ceremonial use of incense did not arise there. Such are some of the anthropological questions raised by a study of the flora of the Lower Nile Valley.

Symbiosis in Animals and Plants.

Prof. George H. F. Nuttall's address to Section I (Physiology) dealt with (1) Symbiosis in plants: lichens; root-nodules of leguminous plants; the significance of micorhiza in various plants, especially orchids; and (2) Symbiosis in animals: Algæ as symbionts in various animals; symbiosis in insects; micro-organisms in relation to luminescence in animals. The subject is one of broad biological interest, an interest that should appeal equally to the physiologist, pathologist, and parasitologist. It is a subject on which much work has been done of recent years, and information relating thereto lies scattered in the scientific literature of different countries.

The term symbiosis denotes a condition of conjoint life existing between different organisms that are benefited to a varying degree by the partnership. The condition of life defined as symbiosis may be regarded as balancing between two extremes, complete immunity and deadly infective disease. Symbiosis has doubtless originated from parasitism. One condition merges into the other, there being no line of demarcation to separate them. Some organisms supposed to be symbionts to-day may prove to be parasites on further investigation. Certain structures that have been described in the past as normal intracellular bodies in animals and plants have in a number of cases been shown to be micro-organisms which can be cultivated or symbionts that are transmissible hereditarily from host to host. The address constitutes a summary of what is known to-day of symbiosis in the animal and vegetable kingdoms. Apart from its scientific interest, the economic importance of studies on symbiosis is exemplified by what has been established, on the botanical side, with regard to the root-nodules of leguminous plants, the germination of orchids, and the origin of tubers.

Mental Differences between Individuals.

The address by Dr. Cyril Burt, president of Section J (Psychology), deals with the mental differences between individuals, with special reference to applied psychology in education and industry. The most remarkable advances made by psychology during recent years consist in the rapid development of what threatens to become a new and separate branch of science; namely, the study of individual differences in mind. The numerous data collected from various fields of applied psychology—from the psychology of education, industry, and war, of mental disorder, deficiency, and crime—are now sufficiently extensive and trustworthy to deserve co-ordination into a single systematic body of knowledge.

Early pseudo-scientific attempts to diagnose mental characteristics from physical and other signs were misled by an inadequate technique. The true procedure was supplied by Sir Francis Galton, who applied to the general problem two special methods of inquiry—the statistical method of correlation, and the experimental method of psychological tests. These in turn rest upon a fundamental assumption, which recent work has verified—the continuity of mental variation. This is the keystone of individual psychology as a science. The differences between one man and another are always a matter of "more or less," seldom, if ever, a question of presence or absence or of "all or none." There are no such things as mental types; there are only mental tendencies.

The general scheme under which individuals are to be studied is much the same, whether they are normal or supernormal, backward, defective, or delinquent, or ordinary applicants for vocational guidance.

The positive foundations for a practical psychology of individual differences have been laid in three broad generalisations, each the separate suggestion of recent experimental work. These consist in a trio of important distinctions: the distinction between intellectual and emotional characteristics, between inborn and acquired mental tendencies, and between general and special capacities. The future progress of individual psychology will consist chiefly in devising more exact methods for examining mental qualities under each of these respective heads.

Aspects of the Study of Botany.

Mr. A. G. Tansley's presidential address to Section K (Botany) deals with some aspects of the development of pure botany during the last thirty or forty years, especially in the British Isles. By means of quotations from representative botanists of the last decade of last century, the views held at that time on the relation of morphology and physiology—that they were two independent "disciplines" or branches of botany—are illustrated. It is pointed out that little progress has been made towards realising the idea of determining the "genealogical tree" of the plant kingdom, and this not so much from the fact that our knowledge is still incomplete, as because, in the recent words of a great authority, it has become evident that the past development of the plant kingdom is represented by

"a series of separate lines, some stretching into a remote past, others of more recent origin," and "it would almost seem that 'missing links' have never existed." The increasing doubt as to whether many organs formerly regarded as homologous are really homologous in the strict sense is mentioned, and it is suggested that our increasing, though still rudimentary, knowledge of the factors that determine organic form will lead us to expect a recurrence of the same formative factors, producing similar structures, on different lines of descent, independently of particular life conditions.

The so-called "Neo-Darwinian" account of evolution is then stated, and its weak points indicated; and a description of the changes brought about by the work of Mendel and his followers, of De Vries and of Johannsen, leads to an attempt to form a picture of the origin of species in the light of present knowledge. It is shown that the problems of phylogenesis and ontogenesis are necessarily interlinked, and it is suggested that in the causal study of development of the individual lies the best hope of determining eventually the real nature of the "genes" which geneticists must postulate to account for the observed phenomena of inheritance.

Emphasis is laid on the view that the central and vital part of biology is, and must be, the study of process, and it is suggested that only by stressing this point of view, especially in elementary teaching, will it be possible to retain the power of looking at the science of plants as a whole and thus of checking the disruptive tendencies which have led to the segregation of different branches of the subject.

The Education of the People.

Prof. T. P. Nunn, in his address to Section L (Educational Science), pointed out that the aim of popular education is to train the young to conserve and develop those elements in the tradition of national life and activity which are consciously judged or instinctively felt to be of most worth. Its content will, therefore, always express the distinctive *ethos* of a nation, and, in particular, will reflect the prevalent view as to the proper relation between the individual and the social body. Assuming that in Great Britain we are committed to the ideal of equal citizenship for all, the ultimate aim of our schools must be to bring all children effectively under the influence of those currents in our cultural tradition which have the greatest and most enduring value. Consideration shows that these must include, in addition to our typical traditions of character and manners, the traditions of creative activity represented in literature, science, and the fundamental arts and crafts. The aim thus indicated cannot be achieved so long as education ends for most boys and girls at fourteen; but it does not necessarily imply a "grammar school curriculum" for all. A technical training, provided that it embodies some dignified tradition of intellectual, aesthetic, or practical activity, satisfies the criterion laid down. It is, however, essential that all education should be liberal in outlook and scope.

Science and the Agricultural Crisis.

The main purpose of the presidential address delivered by Dr. Charles Crowther to Section M (Agriculture) is to indicate some of the directions in which immediate help towards the alleviation of the agricultural crisis can be given by the man of science, and some of the lines along which development of our scientific and educational organisation is more especially necessary at this juncture.

The most fundamental of all kinds of assistance that science can give the farmer is that furnished by way of research, but this must of necessity be slow in development, and dependent for the dissemination of its results throughout the industry upon an extensive and efficient advisory organisation in close touch with the farmer.

Similarly also any raising of the standard of farming through formal education can only be effected gradually, and the conclusion is reached, therefore, that the most hopeful way of rendering assistance quickly is through advisory work. The root difficulty of agricultural educational work in the past has been to secure a sufficiently intimate and widespread contact with the farmer, and for this purpose no agency at our command is so valuable as advisory work, involving as it does a contact with the individual farmer which is both direct and sympathetic, originating indeed in most cases out of a direct request for help.

Rapid progress through advisory work postulates, however, a far more numerous staff of advisers than are available at present, some counties being indeed totally unprovided for, while in many others the advisory staff consists of only one man in the person of the County Agricultural Organiser. It is here where the next extension of facilities should take place. In relation to the organisation operating in direct contact with the farmer, research and organised education are for the time being adequately developed—the latter indeed producing now a considerable surplus of trained men for whom employment in educational work is not available. This in itself implies a certain loss of proportion in the development of the whole agricultural educational organisation, and is to be remedied by the extension of the base upon which the whole structure rests, which is constituted of advice, elementary agricultural education, and propaganda. At the same time a closer degree of co-ordination and co-operation between the various elements of the educational organisation is desirable.

In conclusion, although advisory work may be our most effective means of rendering immediate help, a more permanent contribution to the future prosperity of British agriculture will be made through our educational system in the training of the farmers of the future. As yet we have not succeeded in persuading the general body of farmers that technical education is an essential element in the training of the young farmer. The natural development of such a conviction must perhaps be slow, but might be greatly accelerated if more importance were attached to scientific training as well as practical experience in the letting of farms.

The Ministry of Health.

TRUE versatility is a very wonderful thing, a fit object for the admiration of crowds. History, which is life, offers few examples of true versatility, but what history omits Shakespeare supplies and modern governments assume. Thus the Henry of poetry:

> Never was such a sudden scholar made. . . . Turn him to any cause of policy, The Gordian knot of it he will unloose, Familiar as his garter.

In modern governments, too, abstrusest specialisms must be presumed to grow " like the summer grass, fastest by night." Although Sir William Joynson-Hicks had already held three governmental positions within a year, it may not have been the poetical parallel that has just led to his appointment as Minister of Health; it may have been the old, outworn, Platonic view of the abilities, or absence of them, essential to a statesman; or even mere political exigency. Of one thing we are sure, that the development of a young but vitally important Ministry has been delayed, we hope only temporarily, by the appointment. If a surgeon should ever be offered the woolsack, there is not a lawyer but would deem his previous courses to have been very vain indeed; but to bestow the title of Minister of Health upon a layman evokes singularly little comment. We must be richer than we imagine we are in political genius if the solution of such problems as the inception of an administration of state medicine can be taken up, in a social organisation of such magnitude and complexity as our own, at the rate of four a year. But there is, to the public view, an appearance of difference between the legal and the medical cases, which must be examined and understood before we can proceed intelligently towards an improved condition of affairs.

This aspect of the matter has never been analysed more shrewdly than by Sir Lenthal Cheatle, who, so long ago as last January, set forth to defend the Ministry of Health from the Ministers in the *Nineteenth Century and After*. In his balanced and moderate exposition there is not a loophole left for political control of the office, because the sole reason for political control is objection to medical control, and of such objection nothing survives Sir Lenthal Cheatle's examination. He realises that Dr. Addison's appointment—a purely political appointment, by the way—did not prove, in the opinion of many people, to be a good one. There have been lawyers who have held the Lord Chancellorship and failed in it, lawyers who have held the Premiership and come to grief, lawyers who have held the Irish Secretaryship and brought grief to others; but it is still considered right and proper to appoint a lawyer Solicitor-General, although of Solicitors-General some

have been better than others. Sir Lenthal Cheatle realises that a man can be a good Minister of Health and a bad political tub-thumper, or a great doctor and a bad Minister of Health. He realises that the members of the medical profession actually in the House of Commons, and available for so great a post, are very limited in number, and that occasions may arise when the kind of man wanted would have no seat. Most of the medical members of the present Parliament are there because, first or last, they are politicians, and between them they represent every party opinion in the House. They are not there because politics is the high road to professional advancement. It is not. It is a hobby for medical men who are also men of leisure, the politically minded representatives of politically minded constituencies, who, happily, bring into the deliberations of Parliament, nevertheless, a wealth of special knowledge valuable to the community.

We fail to see in any one of these circumstances an irremediable defect in medical representation or an insuperable barrier to the appointment of a Minister able to direct the first steps of the nation along the pathway to a socially organised health and fitness. But that path is not one of forensic argument. It is one of vision and discovery, possible only to him whose mind is well prepared for the germination of the creative idea by long and close familiarity with the discipline of his science at first hand. Nor must he be sunk beneath the weight of problems of policy and administration foreign to his office, or deprived of jurisdiction essential to its unity. Sir Lenthal Cheatle is right in asserting that the truth, dignity, and force of the public utterances of such an office would themselves advance the cause of health and instruct and benefit mankind. The requisite ability is one that is typically British, exemplified in every department of our Colonial administration, and particularly in the rise of the science of tropical medicine, which is state medicine, under the guidance of British workers.

Possibly it is true that the medical profession itself, having arrived at a clear perception of its functions in modern social life, has not realised how it can make them properly effective. But this opens up questions of great complexity concerning professional and public psychology, both separately and in relation to each other. The pendulum of popular opinion concerning medical men swings from excess to excess through ignorance. In moments of personal thankfulness a doctor is a saint; in moments of collective contemplation he is sometimes worse, but never better than a wordy fool. The people have invented proverbs about doctors, as they have invented proverbs about everything they distrust: proverbs about their differing and about their mistakes. But let a man go to his doctor, or his doctor come to him—a sort of reconciliation occurs. It is a wider thing than it looks, for at heart it is a reconciliation between life and science. The burden of achieving that same reconciliation in politics must fall mainly on the shoulders of the medical profession. Its members we should describe at present as inarticulate rather than dumb, for the medical profession is, after all, a thing of vast subdivisions. Medical science and the profession are not interchangeable terms, and the battle is not the doctors' alone, but theirs for science and the advancement of social life.

Time lived and Time represented.

Durée et simultanéité : à propos de la théorie d'Einstein. Par Henri Bergson. (Bibliothèque de Philosophie contemporaine.) Deuxième édition, augmentée. Pp. x+289. (Paris : Félix Alcan, 1923.) 8 francs net.

WHEN M. Bergson published the original edition of this book last year, he refused to allow its translation because he regarded the work as tentative. It was the result of a special study, which had required a setting aside of purely philosophical research in order to concentrate on mathematical problems. The effect of his intervention in the relativist controversy, which he recognised to be vital in its bearing on the future of mathematics and metaphysics, could not be foreseen. He has now published a second edition, and while he has not found it necessary to revise or alter or modify the first, he has added three appendices, which not only greatly enhance the value, but also enable him in a most striking way to reconcile, and bring into harmony, his theory of time as fundamental reality, l'étoffe même de l'univers (" il n'y a pas d'étoffe plus résistante ni plus substantielle "), with the principle of relativity, according to which time is a variable coefficient, entering with variable spatial coefficients into infinite systems of reference.

The first edition of the book was reviewed in NATURE of October 14, 1922. The review led to a correspondence which is interesting in the fact that it concerned the problem which has called for the new matter in the second edition. This new matter is contained, as we have said, in three appendices, which, though each is complete with its own separate topic, are sequential in the argument and cumulative in force. The first deals with the interesting paradox, " Le voyage en boulet." A very striking mathematical demonstration of it is furnished in a letter addressed to M. Bergson, " par un physicien des plus distingués," which he quotes in full. Two observers, Peter and

Paul, are standing together, and each marks the hour 0^h on his synchronous clock. Paul is then carried suddenly outwards from the earth a specified distance and back again in a rectilinear and uniform movement relatively to the earth and at a velocity of 259,807 kilometres a second. On his return, he finds that Peter's clock records 8^h, while his, Paul's, records 4^h, and it is proved by means of Lorentz's formulæ that each clock has quite correctly measured the time of one and the same event.

Bergson's reply to his correspondent is clear and precise, and involves no dispute as to actual matter of fact. He is able to admit the discrepancy in the time represented and also to affirm the identity of the time lived, and yet to reconcile the paradox. He begins by pointing out that the shortening of the time as measured by Paul's clock is point to point analogous to the contracting of Paul's dimensions as his distance increases in Peter's perspective. Does Peter think, he asks, that because Paul diminishes in his perspective he is really becoming the dwarf he appears? He does not, and he need not, and neither need he suppose that Paul's retarding clock is really registering shorter time. Paul's time, like Paul's dimensions, is the time *represented* by Peter as that which belongs to a system of reference which is not Paul's, but Paul's-system-in-uniform-translation-relatively-to-his-own. It is only Paul's system for Paul when he is immobilised in the system. The paradox arises from supposing that Peter is immobilised in his system of reference, that Paul similarly is immobilised in his, and that the two systems, *while immobilised*, are moving relatively. There is only one time lived, and that is the time of the system in which the observer is immobilised. This may be Peter or it may be Paul, but if it is Peter, Paul's time is *represented* time for Peter, and *vice versa*. Bergson's conclusion is: the formulæ of Lorentz quite simply express what must be the measurements *attributed* to the system S′, if the physicist in system S is to *imagine* that the velocity of light is the same for the physicist in S′ as it is for him in S.

The second appendix deals with the reciprocity of accelerations. Is there perfect equivalence between relative systems of movement when, as in the shock experienced at the sudden stopping of a train, there is a psychical experience which has itself no equivalent? In other words, can there be pure reciprocity in accelerations when certain of the phenomena concern only one of the systems? The argument of this appendix is especially important, and illuminates for the first time a very puzzling position. Stated briefly, it is as follows. If we analyse the acceleration and fix its elements as a succession of represented systems, each in its turn being a system S′ with represented time t' in relation to an immobilised system S with real time t, then the reciprocity is simple and complete; any system which in relation to a system S is a system S′ can itself be a system S, provided that when S′ changes to S, t' becomes t. The symmetry is perfect. But we, on the contrary, are continually representing to ourselves one immobilised system S, to which we oppose a multiplicity of distinct systems animated by various movements, although we still represent them as one unique system S′. When the passenger is thrown from his seat by the sudden stoppage of the train, it is because the material points of his body do not preserve invariable positions in relation to the train. There is no dissymmetry, but instead of a reciprocity between S with t and S′ with t', we have to make the real time belong successively to S″ with t'', S‴ with t''', and so on. The complexity may be infinite, and what we are trying to do is then to make one immobilised system S reciprocal with infinite systems considered not as infinite but as one and unique.

The most important appendix is the third: it deals with real time and world-lines ("Temps propre et ligne d'univers"). It is not possible to abbreviate the argument, which must be read; here we can only indicate its nature. It takes its start from an equation quoted in full from Jean Becquerel. Given a material system of reference, all the points of which are in the same state of movement (*i.e.* any portion of matter in which the spatial distance separating events is null), the time between two events which an observer will measure is the time τ proper to the system, the time which its clocks are registering. A clock in a moving system (whether moving uniformly or non-uniformly) measures the length, divided by the velocity of light, of the arc of the world-line of the system. This principle is worked out to show that in a system in uniform translation (the earth, for example) two clocks to be identical and synchronous must be in the same place. Let one be suddenly and rapidly displaced, and at the end of a certain time (the time of the system) be replaced, it will be found to be retarded. Bergson accepts Becquerel's demonstration (barely indicated here because the mathematical equations are omitted), and proceeds to show how the physicist and the philosopher have each a distinct interest; the physicist must represent a time which is infinitely variable, the philosopher must affirm a time which is absolute and lived. The two interests must be respected and can be reconciled.

Finally, Bergson considers Einstein's case of a field of gravitation produced by the rotation of a disk. In such a system, he quotes Einstein as saying, "It is impossible to determine time by means of clocks which are immobile as regards the system." But is

it true, asks Bergson, that the disk constitutes *one* system? It is only a system if we suppose it immobile; but in that case we are placing a real physicist on it, and then on whatever point of the disk we immobilise this real physicist with his real clock, we have the time which is one and lived. In short, we have to choose. Either the disk is thought of as rotating, and then gravitation is resolved into inertia. This is how the physicist *represents* it, and not as it is for him living and conscious; but then the times measured by the retarded clocks are represented times, and of these there is infinity; the disk will be a multiplicity of systems. Or else this same rotating disk is thought of as immobile. Then inertia at once becomes gravitation. The real physicist now lives its time, and so considered time is one and the same everywhere.

The importance of the book from the point of view of philosophy can scarcely be exaggerated. It accepts frankly the paradox of relativity, goes behind it, and exposes it. The retarding of clocks in systems accelerated relatively to the observer's immobilised system is shown to be a case in point of the relativity of magnitudes. Just as the real dimensions of an object are its spatial magnitudes for an observer immobilised at that point of the universe at which the object is, so the time τ belonging to any system is the time lived by an observer immobilised in that system. For every immobilised observer the times and spaces of other systems are infinitely variable, but these variations are perspectives, represented not lived.

H. WILDON CARR.

Projective Geometry.

(1) *Principles of Geometry.* By Prof. H. F. Baker. Vol. 2: Plane Geometry, Conics, Circles, Non-Euclidean Geometry. Pp. xv+243. (Cambridge: At the University Press, 1922.) 15*s.* net.

(2) *Higher Geometry: An Introduction to Advanced Methods in Analytic Geometry.* By Prof. F. S. Woods. Pp. x+423. (Boston and London: Ginn and Co., 1922.) 22*s.* 6*d.* net.

(3) *Elements of Projective Geometry.* By G. H. Ling, G. Wentworth, and D. E. Smith. (Wentworth-Smith Mathematical Series.) Pp. vi+186. (Boston and London: Ginn and Co., 1922.) 12*s.* 6*d.* net.

(1) CHRISTIAN VON STAUDT'S "Beiträge zur Geometrie der Lage" was published so long ago as 1857; about the year 1871 Felix Klein wrote a series of papers emphasising the fact that it is possible to build up, on von Staudt's lines, the whole of projective geometry, independently not only of axioms of parallelism but also of the notions of distance and congruence. Yet it is astonishing how little effect this discovery has had upon English treatises on projective geometry, which still, with very few exceptions, base their subject upon metrical geometry, and are content to prove purely projective properties of conics by "projecting into a circle." There are, it is true, Whitehead's two tracts on the "Axioms of Projective Geometry" and "Axioms of Descriptive Geometry," but these, as their titles imply, deal only with the logical preliminaries. There is also G. B. Mathews' "Projective Geometry," which suffers rather from undue compression and somewhat confuses the issue by talking about infinity so early as Chapter II.; and there is the important two-volume treatise by Veblen and Young, which is certainly not for the ordinary man.

There was obviously room for a lucid and logical account of the whole of the more elementary parts of geometry, conics, and quadrics and cubic surfaces, developed from the projective point of view, and that is what Prof. Baker's series on the "Principles of Geometry," of which this is the second volume, aims at supplying. Its publication, then, is an event of the greatest importance. Prof. Baker believes that much time "could be saved by following, from the beginning, after an extensive study of diagrams and models, the order of development adopted in this book; and such a plan would make much less demand upon the memory" than does the traditional treatment. Is it not about time that some such course were adopted for University students of scholarship standard in their first year? The ideas involved are, perhaps, difficult, but not more so than those which the Cambridge freshman is expected to assimilate from lectures on analysis.

In the first chapter a conic is defined in the usual way as the locus of the intersection of corresponding rays of two related pencils of lines in the same plane; next, Pascal's theorem and the theory of polarity are developed; and then there are forty most interesting pages of examples of the application of the foregoing theorems in various directions. The theory of outpolar conics, Poncelet's theorem and Hamilton's extension of Feuerbach's theorem may be mentioned. Chapter II. summarises properties of conics relative to two points of reference, and gives a number of results containing those usually developed as consequences of the notion of distance. The terms current in metrical geometry, *perpendicular*, *circle*, *rectangular hyperbola*, and so on, are used for the sake of clearness, but have here, of course, a much more general meaning, depending upon the choice of the absolute points of reference.

In the first volume of the series an algebraic

symbolism was introduced to accompany the geometrical reasoning; in the third chapter of the present volume this symbolism is applied to the matters in hand. The symbols employed consist of the iterative symbols, and those derived from them as the irrational numbers of arithmetic are derived from the rational numbers, together with combinations of such symbols of the form $x+iy$, i denoting a new symbol such that $i^2=-1$. In Chapter IV. it is shown that if we introduce certain laws of order of succession, the symbols are, in manipulation, indistinguishable from the complex numbers of ordinary analysis. The distinction between real and imaginary elements is then discussed. The last chapter deals with the notion of the interval of two points of a line, and the angular interval of two lines through a point, defined projectively in regard to an absolute conic, and leads up to a discussion of non-Euclidean geometry. There follow two important appendices dealing with certain configurations of points and lines, and, in particular, with the complete figure of Pascal's theorem, which is best considered from four dimensions.

Much of the matter contained in this work is, of course, familiar enough, though often presented from a new point of view; in places, especially in Chapter III., extreme condensation of treatment makes difficult reading, but one can browse with pleasure and profit from almost anywhere in its pages, and surely that is a test of a good book. The printing and diagrams are excellent, as one would expect from the Cambridge University Press; we would like to single out for special mention the frontispiece, the Hexagrammum Mysticum, which any one who has tried to draw the figure will recognise as simply marvellous.

(2) Going on from Prof. Baker's book to Prof. Woods', one feels a little confused. Prof. Woods is concerned with "advanced work in algebraic geometry" and so does not worry about the foundations, but it is rather difficult to determine what his foundations are. One's first impression is that he defines a point (in a plane) by means of three numbers, real or complex, and then the line joining two points x_i, y_i as the set of points $x_i+\lambda y_i$ ($i=1, 2, 3$), which is quite logical, though in Prof. Baker's opinion it "appears to beg one of the main, and most interesting, questions arising in the foundations of geometry," but then, on p. 28, Prof. Woods refers for the proof of the theorem that any linear equation represents a straight line "to any text-book on analytic geometry." This criticism may appear pedantic, but the underlying idea of the book is, very properly, the group concept, and the logical attitude is, surely, to begin with the projective group and afterwards to consider its sub-groups, the metrical group, and so on. Also discussions of non-Euclidean geometry (Chapter VII.) seem a little unsatisfactory if the idea of distance has been present from the beginning.

Prof. Woods' book, however, contains a very great deal of interesting and valuable matter not elsewhere accessible in any one volume. His plan is to study different co-ordinate systems, based upon various geometric elements and classified according to the number of dimensions involved. Thus in three-dimensional geometry he considers first the circles of a plane and then point and plane co-ordinates; in four-dimensional geometry the lines of three-dimensional space, spheres and four-dimensional point space, in each case studying the meaning of the linear and quadratic equations. Contact transformations, tetracyclical and pentaspherical co-ordinates are also dealt with. There are numerous exercises. The author is to be congratulated on his determination to "preserve the English idiom" by not using such a phrase as "a line *on* a point," although this has considerable authority behind it now and was introduced, we believe, by an Englishman. The word "nonminimum" would have looked better, surely, with a hyphen; the extra expense involved in printing could have been saved by omitting the diæresis in the much more frequently occurring word "coördinate."

(3) There is little to say about the third work under review. It is a clearly set out, elementary school-book on projective geometry on the ordinary lines, built up upon a metric foundation and excluding any consideration of imaginary elements. A desire to be simple has led to some doubtful statements, *e.g.* "the greatest number of points of a figure that lie on a line which is not entirely in the figure is called the *order of the figure*." But the book may be recommended as a good example of its class; and there is an attractive Greek alphabet on p. vi. The historical note at the end is not so good as one would have expected in a book with which Prof. D. E. Smith is associated.

F. P. W.

The Distribution of Mental Products.

A Short History of the International Language Movement. By Albert Léon Guérard. Pp. 268. (London: T. Fisher Unwin, Ltd., 1922.) 21*s.* net.

PROBABLY no subject is more distasteful to the average educated Englishman than the question of an "artificial auxiliary language." If he be a literary scholar, he feels insulted; if a man of business and affairs, he is coldly indifferent and incredulous. A few men of science may, perhaps, be mildly curious and politely tolerant. If anything can awaken interest and overcome prejudice, it will be this book written

M 1

by Prof. Guérard, if only by reason of its literary quality and attractive style. But the volume possesses many other merits, since it is by far the best work that has been written on this particular subject. Indeed nothing to compare with it has appeared since the learned and rather ponderous "Histories" of Profs. Couturat and Leau. Moreover, Prof. Guérard takes a wide and dispassionate sweep, considering the respective merits and possibilities of French, English, and Latin, as well as those of the "artificial" languages. Very full information is given with regard to the history and structure of all the more important projects, including, besides the so-called "philosophical" languages, Volapük, Esperanto, Ido, Interlingua, Latino sine Flexione, Idiom Neutral, Panroman, Romanal, etc.

There are three appendices, giving, respectively, a bibliography of the subject, a fairly complete list of all known auxiliary language schemes, and a critical comparison of Esperanto, Ido, Interlingua, and Romanal. There is also an index. Throughout the whole book the author displays a cool and critical judgment, combined with much wit and an incisive literary style. The result makes very interesting reading. He is a firm believer in the possibility (and actuality) of an artificial *auxiliary* language for general human intercourse, and drives his point home by cool reasoning devoid of any vestige of emotional fanaticism. His personal predilections are kept well in the background, though he gives good reasons for preferring a language with an Anglo-Latin etymological basis. Like Dr. Cottrell, however, he is in favour of "getting ahead." Several of the existing systems are, in his opinion, good enough for present work-a-day purposes.

An auxiliary international language is a simple transmitting mechanism for the "distribution and exchange" of ideas and information. It is not a romantic revival or a philological trap for the unwary; but just something of great value and usefulness for hundreds of millions of plain folk, who have not time to acquire real facility in five or six national languages. It is not intended to, and will not and cannot, replace or injure national languages. It comes as no destroyer of the family or national hearth; nor is it the siren music of a denationalised intellectualism, or the fierce breathings of an anti-national proletariat. So the plain decent Englishman need have no fear, though he is often a pretty sincere hater of internationalism. The very word is apt to suggest to him the roaring of some hairy and hydra-headed monster ready to defile the fair green fields of England. Sometimes the prejudice takes another form. The present writer once asked a very distinguished Englishman what he thought about the question of an auxiliary international language. The answer was that he had studied Esperanto, but had given it up because the people who spoke it were not the people he wanted to speak to. The onward march of events will sweep away all such fears and prejudices. Even very distinguished Englishmen use aeroplanes and wireless sets, and are to be found in cinema theatres, and dancing to the strains of a gramophone.

Auxiliary language is not an easy *descensus Averni* or a difficult ascent *per ardua ad astra*. It is not for devil or saint, but for the smooth middle way of life. Nor is it something that exists only in the minds of cranks and idealists, for it is with us here and now, is already much used and advancing rapidly. It is not to be expected that old gentlemen in Club arm-chairs will trouble much about it. The important thing is that teachers might test and develop the idea in the schools. Here in the great workshops of early human development there exists a wonderful field for practical work and for very interesting linguistic and psychological researches. There is, indeed, a veritable gold mine here awaiting those who have the insight and energy to discover and develop it. The phoneticians can render valuable aid with their modern analysis and standardisation of the sounds of human speech, while mathematicians and philosophers need not despise a subject that has deeply interested Descartes, Leibniz, Couturat, and Peano.

(1) A BRIEF glance at the contents of this manual suffices to arouse grave doubts as to the author's knowledge of real prospectors. No one who

has sat by a prospector's camp fire or shared his hardships in the field, who knows the type of tough, hardy fellow who starts out to prospect an unknown country with the customary simple equipment—often nothing more than pick, shovel and pan, a bag of food, and a gun across his shoulder—could imagine that chemical equations and crystallographic systems could be of the remotest use or of the faintest interest to him in any circumstances whatever. It is quite certain that he would grudge even the small space that this book would occupy in his pack, even supposing that he could understand it.

If the author, on the other hand, had in mind the preparation of a work suitable for the trained mining geologist, such a man as might be selected as the leader of an important exploring expedition, then it can only be said that the scientific section of the book is too rudimentary and inaccurate to be of use to him. To give one example: a thorough knowledge of mineral deposits is above everything else the first essential for a mining geologist; our author informs us that M. De Launay's "Traité des gîtes métallifères" "contains everything that is known" of the science of ore deposits. There is, however, no such book as he names; he must mean either M. De Launay's "Formation des gîtes métallifères," or else the "Traité des gîtes minéraux et métallifères" by Fuchs and De Launay, both of which were published in 1893. Few branches of scientific study have made more progress than has this one in the last quarter of a century, and the statement that a book written thirty years ago presents the sum of our knowledge of the subject to-day is altogether misleading.

As regards the rest of the book, it may be said that only a small portion is devoted to matter that could interest a prospector of any type; nearly one-half of it is taken up with a sketch of mining operations with which the prospector has nothing whatever to do. Thus it would probably be of use to him to have a correct drawing and description showing how to construct a windlass, but this is barely mentioned, whereas many pages are devoted to the headgears and winding machinery suitable to a large working mine. In the same way, ventilating fans, rock drills, dressing plant and other appliances necessary for a mine in full operation are described in what is entitled a prospector's manual. We wonder if M. Bresson thinks that a prospector really uses any of these.

(2), (3) These two volumes constitute additions to the series of monographs on mineral resources issued by the Imperial Institute, and follow closely the general scheme adopted in previous examples. There is an opening chapter describing briefly the more important ores of the particular metal under discussion, their mode of occurrence, and the general principles of the metallurgical processes employed for the production of the metal. The general uses to which it is put, its prices over a period of years, and statistics of production and trade movements complete this part. The second chapter describes the chief occurrences of the ores within the British Empire, and a third chapter is devoted to deposits in foreign countries; finally a set of references to the literature of the particular subject concludes each volume.

Of these two books it need only be said that the work has been painstakingly and carefully performed, and that they constitute useful handbooks for those requiring general information upon the sources of supply of the two metals in question. The compilation of the volume on copper ores was no doubt the easier task of the two, because much has been written on the subject of copper, notably the volume on copper issued in 1922 by the Imperial Mineral Resources Bureau, which had, indeed, rendered Mr. Allen's work practically superfluous, seeing that the earlier book has covered the same ground as the present volume. Perhaps Mr. Allen himself felt this, because it is noteworthy that he omits this particular work from the list of references quoted by him. He has also missed a number of important monographs issued by the United States Geological Survey, which are, moreover, cited in the much more complete bibliography attached to the work of the Imperial Mineral Resources Bureau.

Mr. Halse had far less assistance in his task; the Imperial Mineral Resources Bureau had indeed issued a volume on quicksilver in 1922, and this again is not referred to in the bibliography attached to Mr. Halse's volume. We trust that the omissions in each case are accidental and not intentional. The bulletin of the Imperial Mineral Resources Bureau contains far less technical information upon the mode of occurrence of mercury deposits, and Mr. Halse has done this part of his work extremely well. Of course it so happens that no mercury, practically speaking, is produced within the British Empire, so that the Imperial Mineral Resources Bureau was bound to treat the subject in a somewhat summary fashion, thus making Mr. Halse's work decidedly more necessary for those who desire a general knowledge of the mode of occurrence of mercury ores.

(4) Mr. Howard White's work constitutes a popular handbook giving in a compact form the main facts concerning the occurrence, preparation, refining and applications of nickel. It is probably quite true, as the author states in his preface, that "comparatively little is known about nickel by the general public," but it should in all fairness be added that no one desiring such information can have the least difficulty in obtaining it since the publication in 1917 of the elaborate report of

the Royal Ontario Nickel Commission, with which the name of its chairman, Mr. G. T. Holloway, will always be associated. The little book before us is very well written; within the space of little more than a hundred pages it deals clearly and comprehensively with this subject and should prove extremely useful to the non-technical reader, who wants trustworthy general information concerning a metal, the industrial applications of which have been increasing steadily during recent years. To any one desiring such information the book can be heartily recommended.

(5) This work is necessarily entirely different from those already considered; it is a scientific report, addressed to the Colonial Secretary, upon the known copper deposits in the Island of Cyprus and the possibility of discovering others of economic importance. Apart from the economic aspect of the work, it possesses a high degree of historical and antiquarian interest, for it is generally held that the main supplies of copper in early historic times were derived from this island, which is indeed said to have given its name to the metal. The deposits of copper ore now known are, however, of relatively low grade, consisting in fact of cupriferous pyrites rather than of true copper ores, but this fact is not incompatible with the previous existence, at the outcrops of such deposits, of gozzans rich in oxidised ores, with possibly a zone of secondarily enriched sulphide ores immediately below them. Such ores could have been successfully treated in those ancient times, although it may be doubted whether metallurgical skill was equal to the task of extracting the copper from a low grade cupriferous pyrites. Nor would it be at all extraordinary that an industry carried on for some thousands of years should have worked up every trace of available mineral.

The report indicates that there is only one mine of economic importance known up-to-date in the Island of Cyprus, namely, the Skouriotissa mine, worked by an American company, the Cyprus Mines Corporation. The mineral deposit consists of a large mass of cupriferous pyrites, estimated to contain some six million tons of ore assaying apparently between 49 and 50 per cent. of sulphur and between 1·8 and 2·5 per cent. of copper. An English company, the Cyprus Sulphur and Copper Company, holds a concession on the Lymni mine, estimated to contain 2¼ million tons of ore in the form of disseminated cupriferous pyrites, with 19·5 per cent. of sulphur and 1·25 per cent. of copper, which is thus too poor to be capable of profitable exploitation at the moment. A number of prospecting permits have been granted, and the authors of the report state the grounds upon which they consider it quite possible that other payable ore bodies may yet be discovered. The authors may fairly be congratulated upon the publication of an excellent piece of work, which will interest equally the mining geologist and the archaeologist.

HENRY LOUIS.

Our Bookshelf.

Liverpool Marine Biology Committee. L.M.B.C. Memoirs on Typical British Marine Plants and Animals. XXV: Asterias. By Herbert C. Chadwick. Pp. viii + 63, 9 plates. (Liverpool: University of Liverpool Press, Ltd.; London: Hodder and Stoughton, Ltd., 1923.) 4*s*. 6*d*. net.

To this useful series of descriptions of common marine animals and plants Mr. Chadwick has previously contributed excellent accounts of Echinus, Antedon, and Echinoderm Larvæ. This description of our common starfish (*Asterias rubens*), with its nine carefully drawn and clearly reproduced plates, even betters his previous performance.

While taking advantage of the large amount of previous work on this well-known echinoderm, notably the embryological observations of Profs. MacBride and Gemmill, Mr. Chadwick appears to have verified nearly all his statements by his own dissection and observation, and when he has not done so he is careful to say as much, as well as to indicate one or two points in which he has been led to differ from the majority. Thus, he does not believe that a single ray can regenerate the whole animal; Helen Dean King, he might have noted, proved twenty-five years ago that to effect this the ray must retain approximately one-fifth of the disc.

On the vexed question of the axial organ and axial sinus Mr. Chadwick "is inclined to support Gemmill's conclusions that in Asterids this system is really hæmal, etc." This may be true physiologically and in part, though some of the evidence, as he admits, is not conclusive; but it does not rule out the morphological interpretation of the organ as a genital stolon, a view, by the way, which is far from having originated with MacBride, as Mr. Chadwick implies. Among the divergent accounts of the minute histology of the eye-spot, that of Cuénot is most in accord with Mr. Chadwick's own observations, but differs from them in denying any lenticular thickening of the cuticle. Though in his diagrams he draws and denotes the apical nervous system, "the writer has been unable to find any trace of this system in any of the large number of serial sections examined by him."

One or two points of terminology are open to question. If, as is generally admitted, the terminals are homologous with the [first] radials of Crinoidea, it is puzzling to call the plates which lie proximally to them the first, second, etc., radials; they correspond to the superbasals of Acrocrinus. The rays are numbered according to the method of MacBride and Gemmill. The method which I based on the primary water-pore as a fixed point, and which Sedgwick adopted as conducing to clearness and precision, is, in Mr. Chadwick's opinion, "worthy of the fullest consideration," but he does not seem to have given full consideration to the criticism of the Gemmill-MacBride system published in my "Studies on Edrioasteroidea." In any

case it is surely confusing to apply the term "anterior" to the anal interradius. Such differences of opinion cannot, however, detract from the value of a book which is essentially a clear and accurate statement of things seen. F. A. Bather.

Les Zoocécidies des plantes d'Afrique, d'Asie, et d'Océanie. Par Prof. C. Houard. Tome 1: Cryptogames, Gymnospermes, Monocotylédones, Dicotylédones (1re partie), Nos. 1 à 1806. Pp. 496. Tome 2: Dicotylédones (2e partie), Index bibliographique, Nos. 1807 à 3293. Pp. 497–1056. (Paris: J. Hermann, 1922–1923.) 2 vols. 100 francs.

During the years 1906–1913, Prof. Houard, professor of botany in the University of Strasbourg, placed all cecidologists deeply in his debt by the issue of his three fine volumes on "Les Zoocécidies des plantes d'Europe et du bassin de la Méditerranée." He has now covered Africa, Asia, and Australasia. Only America remains, and it is to be hoped that Prof. Houard will continue his indefatigable labours and encompass the zoocecidology of the globe. The present work is based essentially on the same plan as its predecessor: a short introduction and table of abbreviations, and then a descriptive catalogue of the animal galls of plants, the latter arranged systematically according to Engler and Prantl's "Pflanzenfamilien." This is followed by a bibliographical index of more than seven hundred memoirs of which Prof. Houard himself may be justly proud to claim sixty-five items; by zoological and alphabetical tables of the animal organisms producing galls on plants, an index of plant hosts, and a general index. The volumes are illustrated by a portrait frontispiece and nearly two thousand figures, which although small are quite adequate.

Three thousand two hundred and ninety-three galls are described, and by his ingenious system of abbreviations, and rather rare power of indicating the chief morphological features in a few words, Prof. Houard manages to convey, often in a line or two of print, quite an astonishing amount of information concerning the structure of the gall, its geographical distribution and the causal agent. To each description is appended the bibliography of the particular gall with a note of the memoirs in which a figure is to be found.

Looking through the bibliography one is a little dismayed to find how little British cecidologists have contributed toward a knowledge of the galls found in lands within the British Empire. There are, of course, exceptions, as the well-known names of Lounsbury, Froggatt, Fuller, Green, Maskell, and others indicate, but one must confess that one would like to see British names a little more prominent and numerous. The volumes are very well produced, and botanist and zoologist alike will thank Prof. Houard for placing in their hands so valuable a contribution to so fascinating a subject.

La Radiologie et la guerre. By Mme. P. Curie. (Nouvelle Collection scientifique.) Pp. 144 + xvi Plates. (Paris: Félix Alcan, 1921.) 8 francs net.

The distinguished author of this little book narrates briefly the part which the X-rays played in the medical services of the French Army during the War, or more correctly the radiological experiences which she herself had during those momentous years as technical director of the radiological work of the Patronage National des Blessés.

The book commences with two short chapters on the nature and production of X-rays. Then follows an account of typical installations employed in hospitals and lorries in the field. A chapter is given up to a description of radiological work in hospitals and is devoted mainly to methods of localising foreign bodies and the examination of fractures. Mme. Curie expresses herself in favour of a preliminary fluorescent screen examination before resorting to photography—a subject on which there is a division of opinion in Great Britain. There is a paragraph on the protective measures essential for the X-ray operator. It is now well known that complete protection may be secured; and in Great Britain at any rate, there has latterly been a steady improvement in the working conditions in hospitals and elsewhere, thanks to the work of the X-ray and Radium Protection Committee and the National Physical Laboratory.

Later chapters in the book deal with questions of personnel and organisation of X-ray departments. Brief mention is made of radiotherapy and radium therapy. As was the case with the British army, when the value of the X-rays had been realised there was an enormous expansion of the French radiological services during the War; and Mme. Curie quotes some striking figures in this connexion. For example, she estimates that in the course of the years 1917 and 1918, well over one million X-ray examinations were conducted by the organisation under her direction.

The nation's appreciation of war achievements is now dulled, but this little book prompts the suggestion that an account of the British radiological activities during the War should be put on record.

G. W. C. K.

Light and Colour. By Dr. R. A. Houstoun. Pp. xi + 179 + 10 plates. (London: Longmans, Green and Co., 1923.) 7*s.* 6*d.* net.

Dr. Houstoun's book deals with wide aspects of the science of light and colour, and will be found of interest by photographers and medical students as well as by members of the public generally. There is an excellent chapter on invisible rays, including a description of Prof. Rankine's method of wireless telephony and Dr. Fournier's optophone, by which a blind man is able to read ordinary printed matter, such as books and newspapers. A very clear and simple account of the X-ray spectrometer is included, and also an account of the current views of the structure of the atom. Primary and complementary colours are described by the author, who gives the usual table of complementary colours—that of Helmholtz—while he states that Helmholtz is not so definite on the subject as is generally supposed: he does not give the defects of Helmholtz's methods, by which indeed no consistent results can be obtained. In ascertaining complementary colours it is absolutely necessary that a comparison white light of known composition be used. Without this there is only a mental estimation of the white, in other words guesswork.

Colour blindness and various methods of detecting

the colour blind are described. In this chapter, as in others, the author shows his appreciation of the physiological aspects of the subject. The section on photochemistry deals with the photographic process, the bleaching of the visual purple, the spectral sensibility curve of *Volvox globator*, and the photo-sensory process of the clam, *Mya Arenaria*. The two concluding chapters deal with phototherapy and dangerous light sources, such as the quartz mercury arc, iron and tungsten arcs, which emit ultra-violet radiations of wave-lengths shorter than 2930 Å.U., and cause a painful inflammation of the eyes and skin. The last chapter deals with the psychology of colour. The book is very well illustrated. F. W. EDRIDGE-GREEN.

Die Fernrohre und Entfernungsmesser. Von Dr. A. König (Naturwissenschaftliche Monographien und Lehrbücher, Band 5). Pp. vii + 207. (Berlin: J. Springer, 1923.) 7*s.* 6*d.*

THIS book expresses the views of one whose academic knowledge is supplemented by considerable practical experience; it contains, therefore, much information that a designer of optical instruments will appreciate. There are three sections dealing comprehensively with the various types and details of telescopes, micrometers, and rangefinders.

The author has unconsciously rather impaired the agreeable impression of impartiality created by the text through the association of the name of his firm with so many of the instruments illustrated. For example, it might be concluded that the well-known design of dial sight which reflects so much credit upon another German firm was attributable to Messrs. Carl Zeiss.

Many of the illustrations have been reproduced from other works and are already well known, and the author has not completely solved the very difficult problem of representing without confusion the paths of rays through prisms of complex form. He describes the theoretical Ramsden eyepiece which has the field lens in the focal plane, but illustrates the practical Ramsden having the field lens f/4 beyond the focus. Too favourable an impression of the practical clearness of optical glass is created by indicating the absorption for $\lambda = 0{\cdot}48\ \mu$. The date and place of Kepler's death as given do not agree with those inscribed upon his tomb, and stereoscopic rangefinders are advocated for reasons that are no longer accepted by responsible German naval officers.

Notwithstanding these and other minor criticisms that might be expressed, Dr. König's book is an excellent one that should prove most useful to all directly or indirectly interested in the science of optical instruments. JAMES WEIR FRENCH.

Die europäischen Bienen (Apidæ). Bearbeitet von Prof. Dr. H. Friese. Lieferung 2. Pp. 113-208 + Tafeln 8-13. 10*s.* Lieferung 3. Pp. 209-304 + Tafeln 14-19. 5*s.* Lieferung 4. Pp. 305-400 + Tafeln 20-25. 5*s.* (Berlin und Leipzig: W. de Gruyter und Co., 1922–1923.)

THE first part of this work has already been noticed in our columns. Parts II. to IV., which have recently come to hand, are devoted to an account of the behaviour, nesting habits, distribution, parasites, etc., of typical members of the various genera of European bees. The classification adopted is essentially biological, bees being treated as solitary, social, and parasitic as the case may be. Perhaps the best feature in the book is the descriptions of the nesting habits, which are accompanied by numerous figures, and practically all the plates are devoted to various phases of this subject. The majority of the illustrations are original and of a high standard of excellence, and many of the plates are exceedingly attractive. The value of others is somewhat marred by the addition of too much extraneous scenery in the shape of hills, roads, etc., as well as buildings. The author's object no doubt is to portray the surroundings in which the species live. The genera Osmia, Halictus, and Chalcidoma are particularly well treated. Chalcidoma occupies no less than six of the plates, but the great genus Andrena scarcely seems to come in for its adequate share of illustration. We look forward to the appearance of the final instalment of the work, and can cordially recommend the parts already issued as a trustworthy and very readable presentation of the habits and economy of the insects of which it treats.

Elements of Natural Science. By W. Bernard Smith. Part 2. Pp. viii + 268. (London: E. Arnold and Co., 1923.) 5*s.* 6*d.*

PUBLIC School science masters have not yet arrived at complete agreement as to how and what science should be taught in general education. The majority of their pupils are not destined for careers and professions in which a definite training in any one branch of science is essential; yet all, in this age which has realised that science is power, should be taught something of the scientific method, and should gain at least an introduction to each of the subjects on which personal and national welfare depend. Mr. Bernard Smith has here made an interesting attempt to steer a safe course between the Scylla of specialist teaching and the Charybdis of smattering, but in places sails perilously near the whirlpool. This Part II. is concerned with electricity and magnetism, astronomy, geology, biology, physiology, and hygiene, and the principles of agriculture. Of these the first three are handled rather more successfully than the others; but throughout the needs of an ordinarily intelligent and well-educated "man in the street" have been kept in mind.

Chemistry, Inorganic and Organic: With Experiments. By C. L. Bloxam. Eleventh edition, revised by A. G. Bloxam and Dr. S. Judd Lewis. Pp. x + 832. (London: J. and A. Churchill, 1923.) 36*s.* net.

THE first edition of Bloxam's textbook was published in 1867. It must evidently have undergone very extensive revision. There can be scarcely a page of the original book left. The revision in the present edition has been wisely and thoroughly done, and the book is one which will be found most useful for reference purposes in schools or institutions where large treatises are not available. It covers the whole of chemistry in an interesting manner, and the descriptions of experiments are especially noteworthy. Many of these were new to the reviewer. The book will probably be found most useful to medical and pharmaceutical students for reference purposes, although it has a wider appeal.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Recoil of Electrons from Scattered X-Rays.

IN a recent paper before the Royal Society (as reported in NATURE, July 7, p. 26), C. T. R. Wilson announced that in his cloud expansion pictures of secondary β-rays produced by X-rays shorter than 0·5 Å, tracks of very short range appear. These electrons, he says, "are ejected nearly along the direction of the primary X-rays."

A quantum theory of the scattering of X-rays, devised primarily to account for the change in wave-length which occurs when X-rays are scattered, led me to predict (Bulletin National Research Council, No. 20, pp. 19 and 27, October 1922) that electrons should be ejected from atoms whenever X-rays are scattered. The idea is that a quantum of radiation is scattered in a definite direction by an individual electron. The change in momentum of the radiation, due to its change in direction, results in a recoil of the electron which deflects the ray. The direction of recoil is not far from that of the primary beam, in accord with Wilson's observation on his short tracks.

Corresponding to this momentum acquired by the electron, it has kinetic energy which varies from 0 when the scattered X-ray proceeds forward, to a maximum value $h\nu . 2\alpha/(1+2\alpha)$, when the ray is scattered backward (P. Debye, *Phys. Zeitschr.* 24, 161, Apr. 15, 1923; A. H. Compton, *Phys. Rev.* 21, 486, May 1923). Here $\alpha = \gamma/\lambda$, where $\gamma = h/mc = 0{\cdot}0242$ Å, and λ is the incident wave-length. The ratio of the maximum energy of a photoelectron excited by an X-ray to the maximum energy of such a recoil electron would thus be $(1+2\alpha)/2\alpha$. But Wilson finds the length of the trails proportional to the square of the energy. The track due to the photoelectron should therefore be $(1+2\alpha)^2/4\alpha^2$ times that of the longest recoil electron tracks.

Taking Wilson's datum that a track of 1 cm. corresponds to 21,000 volts, the equation $Ve = hc/\lambda$ indicates that a ray of wave-length 0·5 Å will eject a photoelectron with a path of 1·4 cm. The recoil electron, taking $\alpha = 0{\cdot}0242/0{\cdot}5$, should accordingly have a range of 0·11 mm., which should just be visible. For his harder X-rays, with a wave-length for example of 0·242 Å ($\alpha = 0{\cdot}1$), the recoil tracks on Wilson's photographs should be as long as 1·7 mm. The quantum idea of X-ray scattering thus leads to recoil electrons moving in the right direction and possessing energy which is of the same order of magnitude as that possessed by the electrons responsible for C. T. R. Wilson's very short tracks.

ARTHUR H. COMPTON.
University of Chicago,
August 4.

As Prof. Compton points out, the phenomena relating to the forward directed β-ray tracks of short range, which appear in air exposed to X-rays of short wave-length, are in agreement with his suggestion that scattering of a quantum may be effected by a single electron.

That the phenomena are in general accordance with Compton's theory was pointed out in my paper (which has now appeared in the current number of the Proc. Roy. Soc.); mention of this was made in my summary of the paper, but was omitted in the abbreviated report of that summary which appeared in NATURE of July 7.

It is obvious that further observations on the range and direction of tracks of this type produced by homogeneous radiations may throw light on some very fundamental questions. The data thus far obtained by this method are not sufficient to decide without ambiguity whether a quantum of radiation scattered by an electron is emitted in one direction only or with a continuous wave-front.

C. T. R. WILSON.
Cambridge, August 24.

Long-range Particles from Radium-active Deposit.

WITH reference to the communication of G. Kirsch and H. Pettersson in the issue of NATURE of September 15, p. 394, on the "Sources of long-range H-particles," the results of an examination by the scintillation method of the particles emitted by radium-active deposit, in which we have been engaged for the past six months, are of interest.

It was found that the active deposit, radium B + C, on a brass disc emitted particles with ranges (in air at 15° C. and a pressure of 760 mm. of mercury) of 9·3, 11·1, and 13·2 cm. respectively, as well as particles of which the range was considerably greater than 18 cm., which were not further investigated, as they appeared to be H-particles. The particles of range 9·3 cm. were previously observed by Sir Ernest Rutherford (*Phil. Mag.*, xxxvii., 1919, p. 571).

Although it would not be possible definitely to decide that these particles were α-rays except by their deflexions in electric and magnetic fields, the appearance of the scintillations strongly suggests that they are α-rays. The numbers of these additional particles were relatively very small; for every 10^7 α-rays of range 6·97 cm. emitted by the source, there were present 380, 126, and 65 particles of ranges 9·3, 11·1, and 13·2 cm. respectively, together with about 160 long-range H-particles.

To ensure that these long-range particles were not produced by collisions by the 6·97 cm. α-particles with air molecules, the experiments on the 11·1 and 13·2 cm. particles were repeated, using carbon dioxide in place of air. In this case the equivalent ranges in air were found to be 11·3 and 13·6 cm. respectively, the agreement being considered satisfactory, as the measurements in carbon dioxide were not made with the same precision as in air.

Moreover, these particles could not have been excited in the mica sheets which were used to provide screens of various stopping powers, for the majority of the experiments were carried out with air or carbon dioxide gaps between the source and the mica, sufficiently large to prevent the 6·97 cm. α-rays from reaching the mica.

The particles under consideration appeared to be independent of the metal on which the deposit was formed, as a check determination of the range of one set of particles, emitted from an active deposit on a platinum disc, gave a value of 11·2 cm.

It seems possible, therefore, that the 12, 13, and 10 cm. H-particles which Kirsch and Pettersson considered to arise from the collisions of α-particles from their emanation tubes with atoms of beryllium, magnesium and lithium, respectively, are actually long range α-particles emitted by the active deposit. It is of interest to note that, should the particles of range 13·2 cm. later prove to be α-particles, they will be the longest range α-particles yet discovered.

Further details of our results and experimental

arrangements will be published when we have completed the examination of the long-range particles from the active deposits of actinium and thorium.

L. F. BATES.
J. STANLEY ROGERS.

Cavendish Laboratory, Cambridge,
September 15.

The Intermediary Hosts of the Human Trematodes, *Schistosoma hæmatobium* and *Schistosoma mansoni* in Nyasaland Protectorate.

I HAVE received a letter enclosing two tubes containing specimens of five species of fresh-water molluscs from Capt. W. H. Dye, Medical Officer, Karonga, Nyasaland, British Central Africa. Capt. Dye writes: "I think I can say that the enclosed specimens represent all the fresh-water molluscs to be found in this district, as I have searched most thoroughly."

Capt. Dye was able to infect two of the species experimentally with *Schist. hæmatobium* and *Schist. mansoni* respectively.

The molluscs have kindly been identified as follows by Mr. G. C. Robson, Zoological Department, Natural History Museum, S. Kensington.

(1) *Lanistes affinis*, Smith (full grown and young).
(2) *Vivipara robertsoni*, Frauenfeld.
(3) *Limnæa natalensis*, Krauss.
(4) *Physopsis sc. globosa*, Morelet.
(5) *Planorbis sp. near sudanicus*, Martens.

Capt. Dye writes of (4) *Physopsis sc. globosa*, Morelet: "They are very common in the marshy pools, although rather difficult to find owing to their predilection for the muddy undersides of reeds, etc., and their habit of dropping off when the plant is touched. They appear to attract *S. hæmatobium* readily, and large numbers of miracidia disappear out of the tube in which they are put, against the control."

Capt. Dye goes on to describe in detail the experiments he made. He finds that the mollusc dies in two days when heavily infected with the miracidia of *Schist. hæmatobium*, after taking precautions to keep the water as free from decomposition matter as possible. The experiments were repeated several times with the same results. The snails were "not killed by *Schist. mansoni*, but one cannot get such concentration of eggs from fæces as from urine."

As to *Planorbis sp. near sudanicus*, Martens, it is referred to as "the one and only species of planorbis in this part of the world (I have most thoroughly searched). This species is not killed by a heavy infection of *Schist. hæmatobium*," but was "infected from a good heavily infected stool with *Schist. mansoni*."

Capt. Dye sent specimens of infected snails, but they died *en route* and were too decomposed for sectioning on arrival. He appears to have discovered that *Physopsis sc. globosa*, Morelet, is the intermediary host of *Schistosoma hæmatobium* in Nyasaland, and possibly he has also found the intermediary host for *Schistosoma mansoni* in Nyasaland (*Planorbis sp. near sudanicus*, Martens).

The other snails which he sent had, he stated, no attraction for either *Schist. hæmatobium* or *mansoni*.

The One-Host Life-Cycle of *Hymenolepis fraterna*, Stiles, of the Mouse.

IN the recently issued third volume of "The Practice of Medicine in the Tropics," edited by Byam and Archibald, Drs. Clayton Lane and Low call in question (on pp. 1821–2) the one-host account of the life-cycle of the well-known tapeworm *Hymenolepis fraterna*, Stiles. This account is principally based upon the work of Grassi and Rovelli and Joyeux, and it is of considerable interest and importance to be certain of the facts, not only because the vast majority of tapeworms in the higher animals most certainly require two hosts in order to complete their life-cycle, but also because these facts have a practical bearing upon the problem concerning the mode of transmission of *Hymenolepis nana* in man.

To ascertain the truth of the matter I have during the last three months selected from a large number of tame mice thirty-four individuals which I have had under close observation for periods varying between 33 and 55 days, during which the fæces had contained no Hymenolepis eggs, and from which it may be concluded that the mice were free from Hymenolepis infection. On July 20 I infected twenty of these mice with large numbers of Hymenolepis eggs obtained from naturally-infected mice, leaving the other fourteen mice as controls. Of the twenty mice infected, eighteen were found to contain cestodes in various stages of development when examined from five to twenty-four days after, one (examined only three days after) probably contained cysticeroids, and one only had apparently remained uninfected. The controls remained uninfected. Since these experiments were conducted under conditions which rendered it impossible for fleas, house-flies, or other animals to serve as intermediate hosts, and since all other necessary precautions were taken, it must be concluded that the one-host account of the life-cycle of *Hymenolepis fraterna* is the correct one. The details of these experiments will be published in full at the earliest opportunity.

Polar Climate and Vegetation.

DR. STEFANSSON'S proposition, as put forth in his letter to NATURE of August 4, p. 162, that if either pole of the earth were situated in a lowland area the winter snowfall would be insufficient to produce a permanent ice-cap, is fundamentally based upon the fact that the Arctic lowlands of Canada and Siberia, with a mean annual temperature far below the freezing-point, are yet free from a summer snow-cover and permanent glaciation. This proposition is tantamount to saying that the inner north polar area is permanently glaciated because it happens to be sea, and the south polar area because it happens to be a plateau 10,000 feet high.

That this is essentially a sound conclusion will, I think, appear on a little reflection. Around the North Pole sea-ice forms during the six months night in such quantity that barely half of it can be melted during the six months day, with the consequence that even in July the mean air temperature (as given by Mohn) does not rise above $+30°$ F., or $2°$ below the freezing-point, while the mean January temperature drops to $-40°$ F.—an extreme "continental" range of temperature at a low general level conditioned by the vast expanse of floe-ice amounting to some two-thirds of the area of the polar sea. On the other hand, the mean July temperature of the Arctic lowlands varies with locality between 40° and 60° F., and, as pointed out by Dr. Stefansson, heat spells of 90° in the shade commonly occur.

The great summer cold of the Antarctic Plateau is at first sight more difficult to understand than the less severe summer cold of the Arctic Ocean. The

south polar area, being a land surface, is entirely dependent on snowfall for its glaciation, and the snowfall there is comparatively small, if only on account of the low vapour content of the air in very cold regions. Yet in spite of the exposure of the high plateau to six months' continuous summer sunshine, except in so far as clouds may sometimes obscure it, the cold continues so intense as to preserve the ice-sheet intact. In the first place, it must be remembered that the Antarctic Plateau, though extensive, is small enough to be chilled in the same way as any other mountain uplift in any latitude rising like an island into the *cold of the free atmosphere*, which is not effectively heated by the sun's rays traversing it. In the second place, the snow-surface reflects so much of the incident solar radiation that comparatively little is available for raising the temperature of the snow to melting-point. These two factors account for the severe summer cold of the Antarctic Plateau; but if the major factor were removed, that is to say, if the plateau, retaining its present horizontal extent and its present amount of snowfall, were lowered to sea-level, it is probable, as Stefansson thinks, that the ice-sheet would disappear in summer, permitting grass, or even spruce forest, to flourish, just as in the Arctic lowlands to-day.

That a reduction to sea-level of the Antarctic Plateau would remove the permanent ice-cap is the opinion, moreover, of Messrs. Priestley and Wright, as expressed in the handsome volume on the glaciology of the second Scott expedition (1910-1913), which has just been published. I do not, however, fully support Dr. Stefansson in expecting that a lowland south polar continent surrounded by an ice-chilled ocean would be liable, at least so often, to the high summer temperature of the Arctic lowlands, and for this reason. In the Arctic lowlands of Canada or Siberia hot spells in June and July may be materially assisted by the passage northward of air heated in the continental regions to the south, and on the contrary cool spells with summer frosts may be occasioned by northerly winds off the ice-chilled polar sea.

Dr. Stefansson has pointed out in his letter of August 4 that the temperature is invariably lowered in hot summer spells in the Mackenzie Valley, as compared with places in Alaska, in consequence of a persistent polar wind which blows up that valley. Now this polar wind up the Mackenzie valley in hot weather is just a local monsoon effect created by the great difference of temperature between the heated land and chilly ocean, and is precisely the predominant type of circulation one would expect to be set up by a lowland south polar continent heated by summer sunshine and encircled by an ice-chilled ocean. Instead of the present glacial anticyclone with outflowing winds, inflowing winds chilled by sea-ice would commonly flow in towards the lowland Antarctic continent and bring a good deal of cloud, rain or sleet, so that the occasions when high-air temperatures of 80° to 90° F. could occur during the southern midsummer, December and January, would be less frequent than in the circumpolar Arctic lowlands in the northern midsummer, June and July, and confined to calm clear conditions.

As regards the dependence of Arctic spruce forest on a short hot summer, Dr. Stefansson makes clearer in his "Northward Course of Empire" than in his letter of August 4, that a factor of enormous importance in high latitudes is the constant summer daylight. As a bioclimatic factor, light is equally important with warmth, and it is apt to be overlooked by climatologists that the contrast between summer and winter is just as much one of light and darkness as of heat and cold in middle latitudes and much more so in polar latitudes. Now it was shown so far back as 1893 that in cold latitudes plants require and utilise more diffuse daylight than in warm latitudes. In the Arctic lands not only is the period of continuous, or nearly continuous, daylight much longer than the period of high temperature which is limited to a few weeks, but on account of the low altitude of the sun the ratio of diffuse to direct sunlight is much greater than in the tropics, so that the intensity of diffuse daylight is relatively great, and there can be no doubt that this factor is all-important in permitting vegetation to push much farther north than would be the case if light were not able to some extent to replace warmth in the economy of plants during the Arctic summer.

The "Northward Course of Empire," reviewed in NATURE of June 23, p. 839, by Dr. H. R. Mill, was written to correct exaggerated views concerning the inhospitality of the "Frozen North," and to show the possibility of settlement in the Arctic lowlands. Many interesting philosophical questions are raised therein. For example, if Dr. Stefansson's generalisation is sound to the effect that the negro, beset on all sides by terrible parasitic enemies, can move to the Arctic and remain healthy if suitably protected from the cold, whereas the more robust Eskimo immediately sickens and dies of germ infections if brought south, because in the comparatively germ-free atmosphere of the far north he has developed no resisting power, the thoughtful reader will inquire whether the high and increasing degree of protection from infection which modern hygiene and medicine is affording to civilised races is not being purchased at the expense of that resisting power which enabled them to survive the ignorance and dangers of the past, so that dire results might follow any temporary withdrawal of the protecting hand through some emergency. At all events, it is clear that a sound medical philosophy will have an eye to the dangers of coddling no less than to those of undue exposure to adverse agencies.

Series Spectra in Oxygen and Sulphur.

A FEW months ago I wrote a paper (Abstract, *Physical Review*, 21, 710, 1923) on "New Series Spectra in Oxygen." It was read at the meeting of the American Physical Society in Washington, D.C., last April. Some questions arose there concerning these series because of their rather unusual character. Hence I re-photographed the spectra of oxygen and obtained data that confirm and extend my earlier results. I also studied the element sulphur, which resembles oxygen in its spectroscopic properties, and obtained, for the first time I think, sulphur spectra in the region of wave-lengths shorter than $\lambda 2500$.

OXYGEN.—The new series reported at Washington have been extended from two to seven and from one to six members respectively. No second member of the third series was found. In the series terms listed below, the Fowler notation is used with the modification that P is used instead of p for the common head of the new *triplet* series. This change was suggested to me by Prof. R. T. Birge. The wave numbers of the head oP_{123} of the series are 109833, 109674, and 109607. Only the shortest wave-length of each member is noted, but the others were observed and may be readily calculated from the data given here; $oP_3 - 1S$, $2S$, . . . $7S$ are λ's 1302·27, 1039·26,

976·50, 950·95, 937·85, 930·24, and 925·46 respectively; $oP_3 - 2D$, $3D$, . . . $7D$ are 1025·84, 971·76, 948·73, 936·62, 929·59, and 924·92. The wave-lengths of $oP_{23} - 1s$ are 1355·6 and 1358·6, while the $oP_1 - 1s$ line is definitely absent.

SULPHUR.—In extending the spectrum of sulphur into the extreme ultra-violet, I used dry sulphur dioxide at various pressures in both the receiver and connected discharge-tube of the vacuum grating spectrograph. The following is a brief summary of some of the results obtained. Sulphur dioxide gas has a strong absorption band extending from λ2500 to λ1700 where a narrow and relatively transparent region occurs, and then another absorption band extends from λ1650 indefinitely into the ultra-violet. The fine structure of these bands is now being studied in this laboratory. By using low pressures strong spectra have been obtained even in these regions of absorption. Thus I have photographed the spark and arc spectra of sulphur. The spark spectrum consists of many lines and groups of lines and extends to λ350. The most prominent feature of the arc spectrum is a number of triplets of wide separation and constant frequency difference. I have classified these triplets in series by analogy with oxygen. The series' designation and wave-lengths are: $oP_{123} - 1S$, 1826·35, 1820·53, 1807·42; $oP_{123} - 2S$, 1436·92, 1433·27, 1425·11; $oP_{123} - 3S$, 1326·69, 1323·58, 1316·63. $oP_{123} - 2D$, 1485·53, 1481·66, 1472·99; $oP_{123} - 3D$, 1412·92, 1409·41, 1401·55; $oP_{123} - 4D$, 1313·22, 1310·26 . . . (the last line of this triplet was not observed as it is probably hidden by the strong oxygen triplet in this region). $oP_{23} - 1s$ are at 1914·96, 1900·47, and the $oP_1 - 1s$ line is definitely missing as in oxygen. The common head oP_{123} of these series cannot be accurately calculated from the data using the Rydberg law. Fortunately the term $1s$ has been observed by Meissner (*Annalen der Physik*, 50, 713, 1916) in his study of the infra-red, hence the head of these series and all the other terms may be obtained at once from the above corresponding wave-lengths. Thus oP_{123} has the values in frequency units of 82982, 83156, and 83554. Using these values and the observed wave-lengths, $1S = 28227$, $2S = 13384$, etc. Other spectra in sulphur containing these terms would exist in the region of the infra-red and have not yet been observed.

Both the oxygen and sulphur spectra described above show similar characteristics, namely, the intensities of the lines and their separations are inverted as compared with the known spectra of these elements in the visible and infra-red, thus in the new spectra the shortest wave-length of each triplet is most intense, and, as indicated by the data above, the frequency separation is greater between the two more refrangible lines of each triplet. In both elements one triplet has a missing line correspondingly placed. This fact seems to indicate an inner quantum relation which makes its occurrence impossible.

On the new Bohr theory the valence level of oxygen and sulphur is a 2_2, hence a p or P level and my data indicate this to be a triple level. Apparently there exist one stable and two metastable forms of each of the elements atomic oxygen and atomic sulphur. On the assumption that in both elements the oP_{123} level is the valence level, the resonance and ionising potentials of the stable forms as calculated from the data above are: for the oxygen atom, resonance 9·11 volts, ionisation 13·56 volts; for atomic sulphur, resonance 6·50 volts, ionisation 10·31 volts.

J. J. HOPFIELD.

University of California, Berkeley,
August 3.

[IT should be noted that in the foregoing communication the capital letters P, S, D refer to the new triplet series, and in the case of oxygen are not connected with the previously known "singlet" series for which similar designations have been elsewhere adopted. Also, that the terms $1s$ are those associated with the previously known triplet series of oxygen and sulphur.—ED. NATURE.]

Continental Drift and the Stressing of Africa.

MR. WAYLAND in NATURE of August 25, p. 279, brings forward weighty arguments, based on the results of the Geological Survey of Uganda, to rebut the usually accepted view that the Protectorate, like most of eastern Africa, and probably western Africa as well, has been predominantly in a state of tension. I shall be surprised, however, if further work does not disclose the existence of at least some normal faulting with a north and south strike, showing the former existence of east and west tension. It may well be that compression and tension have more than once alternated with each other in Uganda. There is no reason, too, why a change of conditions may not convert a true rift valley formed in a period of tension into one bounded by reversed faults.

I am by no means prepared to admit that the birth of the moon (supposing it to have in fact arisen by separation from the earth) must have necessarily been a "piece of extremely ancient history." Sir George Darwin gives reasons for his belief that it took place considerably more than 50 or 60 million years ago. Now Dr. Holmes's calculations, based on the uranium-lead ratio of certain minerals, show an antiquity of about 500 million years for the beginning of the Cambrian. This would suggest that the interesting event in question may have occurred at some time within the limits of the fossiliferous record.

Nor is there any reason to believe that it must have been marked by stupendous catastrophic disturbances. A sphere of the earth's size yields itself slowly but practically unresistingly to a force acting continuously upon it—in this case the centrifugal force due to its rotation, accelerated more by the progressive condensation of its interior than retarded by the tidal action of the sun.

The process of separation may have been protracted over a considerable time, more perhaps than that represented by a single geological formation. Indeed, there is a great deal to be said for the suggestion that it may have commenced about the middle of the Carboniferous and continued till the close of the Trias. This would account for the fact that in the portion of the earth's crust which has been chiefly studied, that is to say the extra Pacific area, there appears to have been throughout that lengthy period a general, though by no means a complete, recession of the ocean, which would presumably be attracted towards the protruding mass of the moon. At some stages of this emergence the bulk of the atmosphere would be affected in the same way, giving rise in the region antipodal to the moon to a period of marked rarefaction and cold, resulting in the Talchir and Dwyka ice-age which has been recognised not only in South Africa, but also in India, Australia, the Falklands, and South America, all formerly according to Wegener, and I believe he is right, clustered about Africa. If there be any truth in this supposition we should expect the chief period of tension in Africa and its surroundings to have existed in Mesozoic and early Kainozoic times, not in the Palæozoic or pre-Cambrian. The powerful tidal action of the moon, while still comparatively

near the earth, would be responsible for the fact that the readjustment of the earth's crust after a large portion had been removed in the course of the formation of the moon was mainly effected in an east and west direction.

In these circumstances the excessive meridional folding which Prof. Chamberlin postulates as a necessary result of tidal retardation could not be looked for.

The chief value of the formulation of a speculative hypothesis such as I have sketched out is in illustrating and emphasising the interest and importance of detailed study of geological structures, region by region and period by period, throughout the world. It will only be when we have all the facts before us, that we shall be able to solve with any assurance the problems presented by the present configuration of the surface of the globe.

With regard to the use of the words "rift" and "rift-valley," the latter was originally and properly used by Prof. J. W. Gregory for a structural valley due essentially to tension, and I use "rift" in the corresponding sense—of a split in the earth's crust due likewise to tension. This is in close accordance with the popular and literary use of the word "rift." Should at any future time it be clearly proved that the "great rift valley" was never in the whole course of its existence associated with east and west tension, it would then, I submit, have no longer a right to the title. JOHN W. EVANS.

Stereoisomerism among Derivatives of Diphenyl.

THE cases of isomerism so far recorded among derivatives of diphenyl, whether connected with optical activity or not (Kenner and co-workers, Trans. Chem. Soc., 1922, 121, 614, etc.), are interesting from the point of view of the possibility of the existence of a stable para-bond in benzene and, more particularly, in diphenyl derivatives. Thus, any 2 : 2′-derivative of diphenyl should be capable of optical activity on the basis of the general formula :

```
  /CH=CR\         /CR=CH\
CH--------C---C--------CH
  \CH=CH/         \CH=CH/
```

which reveals the presence of four asymmetric carbon atoms.

From the same point of view, the isomeric dinitrobenzidines (cf. for example, Brady and McHugh, Trans. Chem. Soc., 1923, 123, 2047), and some of the substances derived from them, also contain four asymmetric carbon atoms, although this type does not include cases of optically active substances at present.

The above suggestion opens up a large field for investigation. It is interesting to note, in passing, that diphenyl forms a tetra-ozonide, which may indicate that the para-bonded condition is favoured even by the parent hydrocarbon. E. E. TURNER.

The Liesegang Phenomenon—an Historical Note.

THE discovery of the phenomenon of periodic stratification in gels is attributed to Liesegang (*Phot. Archiv*, 1896, 221). Historical accounts of earlier experimental work on the formation of precipitates of sparingly soluble substances in gels are given by Wo. Ostwald ("Grundriss der Kolloidchemie," Dresden, 1909, 208) and by Bradford (*Biochemical Journal*, 29, 29, 1920). The latter author states (*loc. cit.*, p. 29): "The first observation of a series of layers (produced by periodic precipitation in gels) must be ascribed to Lupton (NATURE, 47, 13 (1892))." It may be observed that Ord published experiments before this date on the formation of calcium oxalate in isinglass gels. Details of these experiments are given in his book ("The influence of Colloids upon Crystalline Form and Cohesion," London, 1879), which, in the writer's opinion, has not received the attention it deserves. It appears from the passage quoted below (*op. cit.*, p. 108) that Ord before 1879 (the actual date of the experiment is given in the text as March 12, 1869) had obtained stratified precipitates of calcium oxalate :

"The deposit (of calcium oxalate) was not uniform, but somewhat stratified, forming a layer of greatest density near the calcium solution, a layer of less density, with some opalescence, near the oxalic solution, *and several intermediate layers of still less density, with alternate spaces of extreme scantiness of deposit.*"

In the light of these facts it seems that the priority of the discovery should be taken by Ord.

Urease as a Product of *Bacterium radicicola*.

THE letter by Prof. Werner in NATURE of August 11 "On the Presence of Urease in the Nodules of the Roots of the Leguminous Plants," induces me to state that urease is also produced by the pure cultures of *Bacterium radicicola*, and much more profusely than by the nodules. Such forms as *Viciæ*, *Trifolii*, *Pisi*, are particularly strong in this respect, while *Ornithopodis* and *Lupini* are but feeble urease-producers.

It is interesting to observe that urease is also, in certain cases, a product of the normal papilionaceous plants, first discovered by Takeuchi in the beans of *Soja hispida*, and by me in the seeds and the rind of the branches of *Cytisus Laburnum* and *Glycine chinensis*.

The simplest way for the demonstration of the enzyme is the plate-method which I have described in *Centralblatt f. Bakteriologie*, 2te Abt., Bd. 5, p. 323, 1893, and *Archives Néerlandaises*, 1895. As, however, *B. radicicola* does not grow well on broth-gelatin, or yeast-decoct-gelatin with $1\frac{1}{2}$ per cent. urea, the detection of the enzyme must be made with material taken from colonies previously grown on peas-leaf-gelatin, with 2 per cent. cane-sugar, and then used as little lumps, placed on the yeast-decoct-urea-gelatin plate. After a few minutes the beautiful "iris-phenomenon" becomes visible if urease is present, as a consequence of the production of ammonium-carbonate which precipitates the calcium-carbonate and calcium-phosphate in the particular manner proper to this experiment. The addition of some calcium-malate to the yeast-urea-gelatin enhances the sensibility of the iris-reaction.

The discovery of urease in *B. radicicola* was the result of experiments on the nutrition of this bacterium, performed in 1919 and 1920, with the cooperation of Mr. Ir. L. E. den Dooren de Jong at Delft. M. W. BEIJERINCK.

Gorssel, Holland.

The Study of Man.[1]

By Prof. G. Elliot Smith, F.R.S.

In this address I propose to give a sketch of the progress that has recently been made in some of the manifold branches of study concerned with the nature and history of man and his achievements, and to suggest how they can be correlated and integrated as a real science of man with a distinctive discipline.

The recent discoveries of the remains of Rhodesian man and the Nebraska tooth have added a new species and a new genus to the human family, and two continents to the known domain of its extinct members. Intensive studies of the whole series of fossil remains and comparison with the living races of *Homo sapiens* have made it possible for us to construct a family tree of the Hominidæ, and to draw certain inferences as to the nature of the evolutionary changes that have occurred within the human family since it first came into existence. From such investigations it appears that some of the features regarded as distinctive of the highest races of men are temporary phases in the lower races; and, what is much more striking, many of the anatomical traits generally supposed to be peculiar to the human family are found in new-born gorillas and chimpanzees, but are lost by these apes before they attain their maturity. Prof. Bolk, of Amsterdam, has recently been studying this remarkable phenomenon,[2] and has attempted to interpret the facts by the Batesonian paradox that man has attained the human status and the higher races have advanced a stage beyond the lower, not by the acquisition of new characters, but by inhibiting the full development of his ancestral traits. I am unable to accept my distinguished friend's speculations. For man's mental powers and the brain that makes their manifestation possible cannot be explained simply as an unveiling of possibilities dormant in his ancestors, for they are positive additions to his equipment which represent his distinctive characteristic. There is, however, this germ of truth in Prof. Bolk's claim; the apes have in many respects departed further from the primitive ancestral type than man has in that they have become more highly specialised in adaptation to a particular mode of life. They have lost not only many primitive traits that man has retained, but also the plasticity and adaptability that played a decisive part in the attainment of man's mental pre-eminence.

I propose here to submit a tentative pedigree of man's Primate ancestry based upon the results of intensive studies in comparative anatomy and embryology, and discoveries in palæontology, and to use this as the basis for a study of the progressive changes in the brain, which prepared the way for the eventual emergence of those attributes of mind which distinguish man from all other living creatures.

In the course of this inquiry we shall see that during the process of evolution man's Primate ancestors wandered from America to Europe and Asia, and that such world-wide migrations have been continued by certain of their descendants ever since, providing the new environments which weeded out those members of the order that failed to adapt themselves to new circumstances or to specialise and drop out of the race for the attainment of a higher status. Nor did this migration cease with the advent of man himself. He has ever been a wanderer upon the face of the earth; and not until the invention of civilisation did certain groups of human beings become anchored in definite localities. One of the great sources of confusion in modern anthropological discussions is the failure to distinguish between the migration of population and the diffusion of culture: in other words due recognition is not given to the fact that a small group of people of a higher culture can impose the latter upon a large community without necessarily effecting any recognisable change in the physical characters of the people as a whole.

The Discovery of Tutankhamen's Tomb.

When the programme for the British Association meeting was first tentatively drafted, more than six months ago, the attention of the world at large was fixed upon the Theban Valley of the Tombs of the Kings, and the name of the insignificant pharaoh Tutankhamen was on every one's lips. The officers of the Association then decided that the evening lecture should be devoted to an exposition of the scientific results of the exploration of Tutankhamen's tomb, and it was hoped that Lord Carnarvon would have presided at it. I need not dwell upon the tragic events which have made impossible the realisation of either of these proposals. Lord Carnarvon's death has dealt a very serious blow to Egyptian studies just at the moment when it is more than ever important that British prestige in Egypt as a serious patron of archæological study should be maintained and strengthened.

The work in Tutankhamen's tomb has yielded singularly little information of direct scientific value. Yet there are certain aspects of this dazzling illumination of the last phase of the eighteenth dynasty that are worthy of attention. I need not emphasise the value of this discovery in forcing upon the attention of the world the vastness of the achievements of the ancient Egyptians in the fourteenth century B.C. At a time when some of us have been trying to impress this fact upon students of anthropology one cannot refrain from acknowledging the debt to Mr. Howard Carter for having accomplished in one winter what we have been striving in vain to do at the British Association for more than twelve years. There is only one point in connexion with this discovery to which I can refer before I turn to consider other aspects of the study of man.

The Search for Gold.

The vast quantity of gold actually found in the tomb is a point of special interest, for it raises problems of the utmost significance with reference to the part played by this relatively useless yellow metal in the history of civilisation. At a time when we have lost the use of gold as currency it is interesting to contemplate a stage

[1] Evening lecture delivered to the British Association Meeting at Liverpool, on September 14.

[2] L. Bolk, "The Part played by the Endocrine Glands in the Evolution of Man," *The Lancet*, September 10, 1921, p. 588.

in history before gold coinage was invented, although the metal was being used as tribute. Gold was the first metal used by man, and it was the arbitrary value attached to it for its supposed magical properties as an elixir of life that initiated the world-wide search for it which has now lasted for sixty centuries, although the motive for the search—in other words, the reason for attaching so peculiar a value to the soft yellow metal—has changed. The search for gold has been the most potent influence in the development and the spread of civilisation. From the pictures in the tomb of Tutankhamen's viceroy Huy, we learn that the gold was obtained from Nubia and the Soudan, and we are also shown the peculiar types of ships which brought this tribute down the Nile. The demonstration of the effects of such exploitation upon the Soudan has recently been revealed by the investigations of Prof. Reisner, which have provided us with an object lesson in the process of cultural diffusion such as has been happening in every part of the world since then. In modern times we have seen it in the Transvaal, in Australia, and in California—the settlement of relatively small bands of miners to get gold and incidentally to plant in hitherto waste places of the earth certain of the elements, good and bad, of our civilisation. In the Soudan thirty-five centuries ago the Egyptians were doing what our own people are now doing in the Transvaal. A relatively small band of people of higher culture were making use of the local population to exploit the gold to which the latter had previously attached no value. As the result of the settlement of cultured immigrants in their midst certain of their customs and beliefs were adopted by the indigenous inhabitants and blended with their own customs. In a report upon Prof. Reisner's work in the Soudan which I submitted to the British Association in 1915 (Report, p. 189) the facts relating to this racial and cultural mixture were summarised.

The geographical distribution of archæological remains and the features of the culture reveal to every one who is willing to read the plain story told by these facts, first emphasised by Mr. W. J. Perry, that the same process has been going on ever since the first civilisation was invented, and that it has been the chief motive for the diffusion of culture throughout the world. Whether one examines the distribution of the earliest monuments in Southern India, or the settlements mentioned in the Rig Veda in the North-West, the distribution of ancient settlements in Persia, Siberia, the Caucasus and Asia Minor, or further afield from the ancient East in Europe and the British Isles, in Africa to the Niger and Zimbabwe, in the lands of gold in Malaysia and Eastern Asia, and further still in America, we can read the same story, the same motive and the same result of the exploitation of the local natural resources by the native population under the direction of relatively small bands of alien immigrants.

Many other materials to which a magical or economic value was attached played a part in this process of exploitation. Resin, timber, pearls, copper, flint, jade, turquoise, lapis lazuli, amber, tin, and eventually all metals, were some of the more obtrusive lures that impelled men to embark upon any adventure, however hazardous: and the search for these things was responsible for the world-wide diffusion of culture.

The investigation of the details of these events throws new light upon ancient history and affords a convincing explanation of much that hitherto has been obscure in the history of civilisation.

Ancient Mariners.

Considerations of time will permit me to refer only to one aspect of this world-wide diffusion. The pictures of the boats used by Tutankhamen's viceroy reveal certain peculiar features which were adopted also in sea-going ships in the Mediterranean and Erythræan Seas. These distinctive methods of ship-building have been preserved until the present day in the Victoria Nyanza in East Africa and in certain parts of the Malay Archipelago. They are also revealed in quite unmistakable fashion in sculptures of the Early Bronze Age in Sweden. Here there is a specific illustration not only of the fact of the world-wide diffusion of culture but also of the chief means by which it was effected.

The New Vision in Anthropology.

The investigation of the factors involved in this demonstration of the unity of civilisation brings to light the motives that prompted its origin, and provides us with a new insight into the real meaning of customs and beliefs. It contains the germ of a new method of approach to the problems of psychology, and a means whereby in time the unification of anthropology will be effected and a real science of man created.

During the last twelve years there has been a profound change in most of the fields of investigation concerned with the study of man. Not only has there been a rich harvest of new facts and a fuller understanding of the meaning of such knowledge as we possess, but also there has begun to emerge a radically new attitude toward the problems awaiting solution. Hitherto the investigator who concerns himself with the problems of human structure and function, of the races of man, of the fossil remains of man, of evolution and inheritance, as a rule has refused to discuss customs and beliefs, arts and crafts, social organisation, and the psychological aspects of anthropology which are now commonly called cultural. The two branches of anthropology have been cultivated in water-tight compartments, and the fact that the results achieved in each of them have far-reaching significance for the interpretation of the problems of the other is as a rule totally ignored.

During recent years some of the more far-seeing students of man have been insisting upon what the late Dr. Rivers called the unity of anthropology and the urgency of the need for more co-operation between the different fields of research.[3] Until such integration is effected there can be no real science of man. In this address I propose to give a sketch of the new trends in anthropological thought, and to suggest how they may be unified and focussed upon a definite aim, the interpretation of man's history and human conduct.

Perhaps a simple illustration will explain the value of the correlation of physical and cultural studies. Twelve years ago, when attempting to interpret the

[3] W. H. R. Rivers, "The Unity of Anthropology," *Journ. Royal Anthropological Institute*, 1922; also B. Malinowski on the same subject, Nature, Sept. 1, 1923, p. 314.

results of the study of ancient Egyptian remains, I plotted out on a map the geographical distribution of an alien people with easily recognisable distinctive features that began to make its way into the Egyptian Delta about 3400 B.C.[4] This people, which played a definite part in Egypt, Babylonia, Crete, and the Mediterranean, and especially in Britain, could be traced without much difficulty to its homeland in Western Asia. Having reached this stage in interpreting the facts, I was greatly perturbed to find that this same unmistakable type was found widespread throughout Polynesia. Having failed to get any help or encouragement from anthropologists, either on the physical or the cultural side, to pursue this subject further, I had no alternative than to resort to ethnological studies to see whether I could not discover cultural evidence to shed some light upon the undoubted facts of race, concerning which I was satisfied that I had unshakable evidence of a widespread migration of people. In Polynesia I found the same general associations between the distribution of these distinctive people and the practices of megalith-building and mummification as I had previously found in the Mediterranean area and Western Asia; and when the evidence came to be studied intensively it seemed to establish upon unshakable foundations the fact of the unity of civilisation and the world-wide diffusion of culture in early times. This conclusion of course has been warmly contested during the last ten years, during which, however, its opponents have repeatedly shifted their ground and taken up new lines of defence. While there is not a scrap of doubt as to the ultimate issue, it is clear that there will be a prolonged conflict such as in the past was necessary to convince people that the earth was not flat, or that man was really evolved from a Simian ancestor.

There are two points in connexion with this theory that I want specially to mention:—(*a*) Its bearing upon the problems of physical anthropology, and (*b*) its relation to psychology. If it can be demonstrated that at certain scattered localities widespread throughout the world the germs of the common civilisation were planted by immigrants, the recognition of the presence of the latter at some places and not at others is a fact of cardinal importance to the student who is attempting to interpret the puzzling results of the intensive study of race in localised areas. When one is dealing with regions like Oceania, where the population is the result of relatively recent immigrations, probably none of them more than twenty centuries old, such considerations are clearly the essence of the whole problem.

I need say no more in justification of the fundamental importance of the close correlation of the work in physical and cultural anthropology. They are parts of one and the same problem, which cannot be solved unless both classes of evidence are given their proper value.

One of the greatest obstacles that has barred the way to such collaboration has been the persistent refusal on the part of ethnologists to distinguish between diffusion of culture and migration of people. The confusion that has arisen from this issue has had far-reaching effects not merely upon the interpretation of the early history of civilisation, but also by implication in creating a bias in favour of the untenable hypothesis that there is a necessary connexion between race and culture.

The proof of the fact of this widespread diffusion of ancient culture is provided (*a*) by the positive evidence that it did occur; (*b*) by the fact that in the history of custom and invention knowledge invariably has spread in the way we postulate, and has ever been the chief incentive to progress in the new foci; and (*c*) by the psychology of invention. If then, it is asked, the fact of diffusion is so certain, why is there so intense an opposition to its admission? Why do the majority of anthropologists cling to a theory that is so obviously false? Their attitude and methods of evasion become more intelligible if one goes back three centuries ago and studies the arguments of the people who refused to admit the error of the flat-earth hypothesis. If it be urged that the opposition in that case was essentially theological, it can be claimed that mediæval theology has not a monopoly of dogmatism against the advancement of science. The errors of ethnological doctrine that still hold the field are largely the outcome of certain incidents in the sixties of the nineteenth century, as the result of which (*a*) the terms used by biologists in the Darwinian controversy were misunderstood and misapplied, and (*b*) in the conflict with such apologists as Archbishop Whately and the Duke of Argyll [5] the ethnologists not only made claims that recent research has shown to be wholly indefensible, but also laid down these false doctrines with all the pontifical air of infallibility which unconsciously they seem to have adopted from their theological opponents. In recent times the attempt has been made to bolster up this false claim by certain specious psychological arguments; and the best hope for ridding anthropological science of so serious a hindrance to progress is to be found in the adoption of serious psychological methods in the investigation of customs and beliefs and the interpretation of the history of civilisation. Nor would the benefit of this closer correlation between ethnology and psychology be one-sided. Psychology has at least as much to gain as ethnology. For the investigation of the meaning of myth and folk-lore, of custom and belief, is coming to play an increasing part in the study of human behaviour. The further development of this tendency is certain to be the chief factor in ridding anthropological studies of the encumbrances of error which still hamper their growth.

MAN'S DISTINCTIVE ATTRIBUTE.

The study of man can only become transformed into a real science when man's really distinctive attribute, the nature of the human mind, is made the chief subject of anthropological inquiry. The value of psychology as the great integrating factor in anthropology has recently been explained with great lucidity by Dr. Malinowski, and in the rest of my address I want to suggest that the extent of its possibilities for effecting co-ordination is even much wider than the claims he made for it. Psychology can become the bond of union between all branches of anthropological inquiry and the medium whereby a distinctive dis-

[4] "The Ancient Egyptians," 1911 and 1923.

[5] Andrew D. White, "A History of the Warfare of Science," etc., vol. i., p. 305 (1920 ed.).

cipline can be developed to justify the creation of a real science of man.

The full recognition of the mechanism of the diffusion of culture involves a new orientation in psychological investigation, for it points the way to the true explanation of the origin of folk-lore and myth and of custom and belief; and it throws a new light upon the springs of human action and upon the problems of social and political organisation and of education. The outcome of this new movement in ethnology will be to effect a closer bond of union with real psychology and through psychology with the biological sciences that are essential for the full appreciation of the meaning of mental evolution.

It is too often forgotten by students of man's evolution that the fundamental distinctive feature of the human family is the nature and range of the powers of mind, which differentiate it from all other living creatures. The chief aim of the interpreter of this evolution should be to offer some explanation of how these distinctively human attributes were acquired.

With his usual facility of expression Sir James Frazer puts this view with great force. It is all the more welcome because he, who so freely uses the theory of the independent evolution of belief, reproves another ethnologist for too exclusive a devotion to biological methods of interpretation and for forgetting "the part that human thought and will have played in moulding human destiny." He says that some of his colleagues "would write the history of man without taking into account the things that make him a man and discriminate him from the lower animals. To do this, to adopt a common comparison, is to write the play of 'Hamlet' without the Prince of Denmark. It is to attempt the solution of a complex problem while ignoring the principal factor which ought to come into the calculations. It is, as I have already said, not science but a bastard imitation of it. For true science reckons with all the elements of the problem which it sets out to solve. . . . In particular, the science which deals with human society will not, if it is truly scientific, omit to reckon with the qualities which distinguish man from the beasts." [6]

It should, then, be the fundamental aim of any movement to integrate the forces of anthropological inquiry to provide an explanation of how man acquired his distinctive position and how precisely his behaviour was modified by the attainment of such heightened powers of discrimination and ability to profit from his experience.

THE EVOLUTION OF THE HUMAN BRAIN.

Intensive research in comparative anatomy and embryology and discoveries in palæontology have made it possible for us to reconstruct man's pedigree with a confidence that hitherto would not have been justifiable. Using this scheme as a foundation, we can determine precisely what structural changes, especially in the brain, were effected at each stage of the progress of the Primates toward man's estate; and in the light of the information afforded by physiology and clinical medicine we are able in some measure to interpret the meaning of each of the stages in the attainment of the distinctively human attributes of mind.

[6] "Totemism and Exogamy," 1910, p. 98.

In an address delivered at the Dundee meeting of the British Association eleven years ago, and elsewhere on several occasions since then, I have discussed this problem: but I make no apology for returning to its consideration again. For, as I have said already, it is the fundamental question in the study of man; and recent research has cleared up many difficult points since I last spoke on the subject.

Even before the beginning of the Tertiary period the trend had already been determined for that particular line of brain development, the continuation of which eventually led to the emergence of man's distinctive attributes. Moreover, man, as I said in 1912, is "the ultimate product of that line of ancestry which was never compelled to turn aside and adopt protective specialisations, either of structure or mode of life, which would be fatal to its plasticity and power of further development."

VISION THE FOUNDATION OF MAN'S MENTAL POWERS.

The first step was taken when in a very primitive and unspecialised arboreal mammal vision became the dominant sense, by which its movements were guided and its behaviour so largely determined. One of the immediate results of the enhancement of the importance of vision was to awaken the animal's curiosity concerning the things it saw around it. Hence it was prompted to handle them, and its hands were guided by visual control in doing so. This brought about not merely increased skill in movement, but also the cultivation of the tactile and kinæsthetic senses, and the building up of an empirical knowledge of the world around it by a correlation of the information obtained experimentally by vision, touch, and movement. The acquisition of greater skill affected not merely the hands but also the cerebral mechanisms that regulate all movements; and one of the ways in which this was expressed was in the attainment of a wider range and an increased precision of the conjugate movements of the eyes, and especially of a more accurate control of convergence. This did not occur, however, until the flattening of the face (reduction of the snout) allowed the eyes to come to the front of the head and look forward so that the visual fields overlapped. Moreover, a very complicated mechanism had to be developed in the brain before these delicate associated movements of the eyes could be effected. The building-up of the instrument for regulating these eye-movements was the fundamental factor in the evolution of man's ancestors, which opened the way for the wider vision and the power of looking forward that are so pre-eminently distinctive of the human intellect. Our common speech is permeated with the symbolism that proclaims the influence of vision in our intellectual life.

The first stage in this process seems to have been the expansion of the prefrontal cortex and the acquisition of the power of voluntarily extending the range of conjugate movements of the eyes and focussing them upon any object. Then came the laborious process of building up in the mid-brain the instrument for effecting these complex adjustments automatically,[7] so that the animal was then able to fix its gaze upon an object and

[7] John I. Hunter, "The Oculomotor Nucleus in Tarsius and Nycticebus," *Brain*, 1923.

to concentrate its attention upon the thing seen rather than upon the muscular act incidental to the process of seeing it. This represents the germ of attention and of mental concentration in general. But the power of automatically moving the eyes with such accuracy that the images of an object upon the two retinæ could be focussed with precision upon exactly corresponding spots made possible the acquisition of stereoscopic vision, the ability to appreciate the form, size, solidity, and exact position in space of objects. It also prepared the way for the development in each retina of a particularly sensitive spot, the macula lutea, which enabled the animal to appreciate the texture, colour, and other details of objects seen with much more precision than before. Hence probably for the first time in the history of living creatures an animal acquired the power of "seeing" in the sense that we associate with that verb. The attainment of these new powers of exact vision further stimulated the animal's curiosity to examine and handle the objects around it and provided a more efficient control of the hands, so that acts of increasing degrees of skill were learned and much more delicate powers of tactile discrimination were acquired. Out of these experiments also there emerged a fuller appreciation of the nature of the objects seen and handled and of the natural forces that influenced the course of events.

With the acquisition of this new power of learning by experimentation, events in the world around the animal acquired a fuller meaning; and this enriched all its experience, not merely that which appealed to the senses of sight and touch, but hearing also. Thus in the series of Primates there is a sudden expansion of the acoustic cortex as soon as stereoscopic vision is acquired, and the visual, tactile, motor and prefrontal cortex also feel the stimulus and begin rapidly to expand. This increase of the auditory territory is expressed not only in a marked increase of acoustic discrimination but also by an increase in the power of vocal expression. At a much later stage of evolution the fuller cultivation of these powers conferred upon their possessors the ability to devise an acoustic symbolism capable of a much wider range of usefulness than merely conveying from one individual to another cries expressive of different emotions. For when true articulate speech was acquired it became possible to convey ideas and the results of experience from individual to individual, and so to accumulate knowledge and transmit it from one generation to another. This achievement was probably distinctive of the attainment of human rank, for the casts obtained from the most primitive brain-cases, such as those of Pithecanthropus and Eoanthropus, reveal the significant expansion of the acoustic cortex. This new power exerted the most profound influence upon human behaviour, for it made it possible for most men to become subject to tradition and to acquire knowledge from their fellows without the necessity of thinking and devising of their own initiative. It is easier to behave in the manner defined by convention than to originate action appropriate to special circumstances.

Within the limits of the human family itself the progressive series of changes that we have witnessed in man's Primate ancestors still continue; and as we compare such a series of endocranial casts as those of Pithecanthropus, Eoanthropus, *Homo rhodesiensis*, *Homo neanderthalensis*, and *Homo sapiens*, we can detect a progressive expansion of the parietal, prefrontal, and temporal territories, which are associated with the increasing powers of manual dexterity and discriminative power, of mental concentration and of acoustic discrimination.

The study of such factors of cerebral development will eventually enable us to link up the facts of comparative anatomy with psychology, and enable us the better to understand human behaviour. Such wider knowledge will, in time, help us to co-ordinate the principles that underlie customs and beliefs, and from such researches there will eventually emerge a distinctive discipline and a more strictly scientific method.

For the full realisation of this vision, what is necessary above all is that the universities should recognise the importance of this new conception of humane studies and take an active part in building up a science of man that is more scientific than what at present are known as the humanities and more human than biology. The fundamental aim of all education is the fuller understanding of the forces of Nature and of human behaviour. The necessity for attacking the latter problem with more directness and precision is urgent; and it is impossible to exaggerate the importance of a fuller cultivation in our universities of the study of the nature of man and of the springs of human conduct. It lies at the root of all knowledge and the intelligent control of all human affairs. I need not emphasise the tremendous practical importance of such studies to an Empire such as ours at the present time. The Pan-Pacific Conference held in Australia recently is an earnest of the realisation of this fact by statesmen and administrators and of the usefulness of collaborating with men of science to acquire an understanding of subject peoples and their social problems. This policy of peaceful development of the Pacific is a good augury for the fuller recognition of the value of anthropology to the world at large.

Some Bearings of Zoology on Human Welfare.[1]

By Prof. J. H. ASHWORTH, D.Sc., F.R.S.

THE bearings of zoology on human welfare—as illustrated by the relation of insects, protozoa, and helminthes to the spread or causation of disease in man—have become increasingly evident in these later years, and are familiar to every student of zoology or of medicine. At the time of the last meeting of the British Association in Liverpool (1896), insects were suspected of acting as transmitters of certain pathogenic organisms to man, but these cases were few, and in no single instance had the life-cycle of the organism

[1] From the presidential address delivered to Section D (Zoology) of the British Association at Liverpool on September 13.

been worked out and the mode of its transmission from insect to man ascertained. The late Sir Patrick Manson, working in Amoy, had shown (1878) that the larvæ of *Filaria bancrofti* undergo growth and metamorphosis in mosquitoes, but the mode of transference of the metamorphosed larvæ was not determined until 1900. Nearly two years after the last meeting in Liverpool the part played by the mosquito as host and transmitter of the parasite of malaria was made known by Ross. In addition to these two cases, at least eight important examples can now be cited of arthropods proved to act as carriers of pathogenic organisms to man—*e.g.* Stegomyia—yellow fever; Phlebotomus—sandfly fever; tsetse-flies—sleeping sickness; Conorhinus—South American trypanosomiasis (Chagas' disease); Chrysops—*Filaria* (*Loa*) *loa*; the flea *Xenopsylla cheopis*—plague; the body-louse—trench fever, relapsing fever, and typhus; and the tick Ornithodorus—African relapsing fever.

In selecting examples for brief consideration I propose to deal very shortly with malaria, although it is the most important of the insect-carried diseases, because the essential relations between the Anopheles mosquito and the parasite are well known. There still remain lacunæ in our knowledge of the malarial organisms. Ross and Thomson (1910) showed that asexual forms of the parasite tend to persist in small numbers between relapses, and suggested that infection is maintained by these asexual stages. Such explanation elucidates those cases in which relapses occur after short intervals, but the recurrence of the attacks of fever after long intervals can only be explained by assuming that the parasites lie dormant in the body—and we know neither in what part of the body nor in what stage or condition they persist. Nevertheless, the cardinal points about the organism are established, and preventive measures and methods of attack based on a knowledge of the habits and bionomics of Anopheles have been fruitful in beneficial results in many parts of the world.

If we desire an illustration of the vast difference to human well-being between knowing and not knowing how a disease-germ is transmitted to man, we may turn to the case of yellow fever. When this pestilence came from the unknown, and no one knew how to check it, its appearance in a community gave rise to extreme despair, and in many cases was the signal for wholesale migration of those inhabitants who could leave the place. But with the discovery that Stegomyia was the transmitting agent all this was changed. The municipality or district took steps to organise its preventive defences against a now tangible enemy, and the successful issue of these efforts, with the consequent great saving of life and reduction of human suffering in the Southern United States, in Panama, in Havana, and in other places, is common knowledge. It is a striking fact that during 1922 Central America, the West Indies, and all but one country of South America were free from yellow fever, which had ravaged these regions for nearly two centuries. The campaign against Stegomyia is resulting, as a recent Rockefeller report points out, in yellow fever being restricted to rapidly diminishing, isolated areas, and this disease seems to be one which by persistent effort can be brought completely under control.

In 1895 Bruce went to Zululand to investigate the tsetse-fly disease which had made large tracts of Africa uninhabitable for stock, and near the end of the same year he issued his preliminary report in which he showed that the disease was not caused by some poison elaborated by the fly—as had been formerly believed—but was due to a minute flagellate organism, a trypanosome, conveyed from affected to healthy animals by a tsetse-fly (*Glossina morsitans*). In 1901 Forde noticed an active organism in the blood of an Englishman in Gambia suffering from irregularly intermittent fever, and Dutton (1902) recognised it as a trypanosome, which he named *Trypanosoma gambiense*. In 1902 Castellani found trypanosomes in the blood and cerebrospinal fluid of natives with sleeping sickness in Uganda, and suggested that the trypanosome was the causal organism of the disease. The Sleeping Sickness Commission (Bruce and his colleagues) confirmed this view, and showed that a tsetse-fly, *Glossina palpalis*, was the transmitter. Since then much has been learnt regarding the multiplication of the trypanosome in the fly and its transference to man. For some years this was believed to take place by the direct method, but in 1908 Kleine demonstrated "cyclical" transmission, and this was shown later to be the principal means of transference of *T. gambiense*. In 1910 Stephens and Fantham described from an Englishman, who had become infected in Rhodesia, a trypanosome which, from its morphological characters and greater virulence, they regarded as a new species, *T. rhodesiense*, and its "cyclical" transmission by *Glossina morsitans* was proved by Kinghorn and Yorke. Recent reports by Duke and Swynnerton (1923) of investigations in Tanganyika Territory suggest that direct rather than cyclical transmission by a new species of Glossina is there mainly responsible for the spread of a trypanosome of the *T. rhodesiense* type.

The impossibility of distinguishing by their morphology what are considered to be different species of trypanosomes, and the difficulty of attacking the fly, are handicaps to progress in the campaign against sleeping sickness, which presents some of the most subtle problems in present-day entomology and protozoology. Here also we come upon perplexing conditions due apparently to the different virulence of separate strains of the same species of trypanosome and the varying tolerance of individual hosts—on which subjects much further work is required.

The relation of fleas to plague provides one of the best and most recent illustrations of the necessity for careful work on the systematics and on the structure and bionomics of insects concerned in carrying pathogenic organisms. Plague was introduced into Bombay in the autumn of 1896, and during the next two years extended over the greater part of Bombay Presidency and was carried to distant provinces. The Indian Government requested that a commission should be sent out to investigate the conditions. The commission, which visited India in 1898–99, came to the conclusion (1901) that rats spread plague and that infection of man took place through the skin, but—and this is amazing to us at the present day—"that suctorial insects do not come under consideration in connection with the spread of plague." Further observations, however, soon showed this conclusion to be erroneous. Liston found in Bombay in 1903 that

the common rat-flea was *Pulex* (*Xenopsylla*) *cheopis*, that it was present in houses in which rats had died of plague and in which some of the residents had become infected, that the plague-bacillus could multiply in the stomach of this flea, and that the flea would—in the absence of its usual host—attack man. These observations pointed to the importance of this flea in the dissemination of plague, and the Second Plague Commission, which was appointed and began work in 1905, definitely proved that *Xenopsylla cheopis* is the transmitter of the plague-organism from rat to rat and from rat to man.

The mechanism of transmission of the plague-bacillus was worked out by Bacot and Martin in 1913. They showed that in a proportion of the fleas fed on the blood of septicæmic mice the plague-bacilli multiply in the proventriculus—which is provided with chitinous processes that act as a valve to prevent regurgitation of the blood from the stomach—and a mass of bacilli is formed which blocks the proventriculus and may extend forward into the œsophagus. Fleas in this condition are not prevented from sucking blood, because the pharynx is the suctorial organ, but their attempts to obtain blood result only in distending the œsophagus. The blood drawn into the œsophagus is repeatedly forced backwards into contact with the mass of plague-bacilli, and on the sucking action ceasing some of this infected blood is expelled into the wound. The transmission of plague depends on the peculiar structure of the proventriculus of the flea and on the extent to which, in certain examples, the plague-bacilli multiply in the proventriculus. Such "blocked" fleas being unable to take blood into the stomach are in a starved condition, and make repeated attempts to feed, and hence are particularly dangerous.

Until 1913 it was believed that all the fleas of the genus Xenopsylla found on rats in India belonged to one species (*cheopis*), but in that year L. F. Hirst reported that the rat-flea of Colombo was *X. astia*, which had been taken off rats in Rangoon, and described by N. C. Rothschild in 1911. Hirst ascertained that this flea did not readily bite man if the temperature were above 80° F. A collection of 788 fleas from Madras City proved to consist entirely of *X. astia*, and Hirst suggested that the explanation of the immunity of Madras and Colombo from plague was the relative inefficiency of *X. astia* as a transmitter. Cragg's examination (1921, 1923) of 23,657 fleas obtained from rats in all parts of India shows that they include three species: *Xenopsylla cheopis*, *X. astia*, and *X. brasiliensis*. This last species is common in the central and northern uplands of peninsular India, but its bionomics have not yet been investigated. *X. cheopis* is the predominant species in the plague areas, while *X. astia* is the common flea in those areas which have remained free from plague or have suffered only lightly. In Madras City, for example, during the twenty-one years, 1897–1917, plague has occurred in twenty of these years, but the average mortality was only 0·013 per thousand—that is, though the infection has been repeatedly introduced there, it failed each time to set up an epidemic. The significance of an imported case of plague depends in large measure on the local species of Xenopsylla. Hirst has made numerous attempts during the plague season in Colombo to transmit plague by means of *X. astia* from rat to rat, but with negative results, and *X. astia* was never found to behave like a "blocked" *X. cheopis*.

The distinction of *X. cheopis* from *X. astia* is not an entomological refinement with purely systematic significance, but corresponds with a different relation of the species to the epidemiology of plague, and hence becomes a factor of great practical importance. If through these researches it has become possible by examination of the rat-fleas of a locality to estimate accurately its liability to plague, anti-plague measures may henceforward be restricted to those areas in which plague is likely to occur, *i.e.* where *X. cheopis* is the predominant flea. Thus a great economy of effort and of expenditure and a higher degree of efficiency may be achieved; in fact, the problem of the prevention or reduction of plague may be brought from unwieldy to practicable proportions. When it is remembered that since 1896 some ten and a quarter millions of people have died in India from plague, we have a more than sufficient index of the importance of a precise knowledge of the systematics, structure, and bionomics of the insect-carrier of *Bacillus pestis*.

Another of the outstanding features of the period under review has been the extensive and intensive study of the Protozoa. The structure and the bionomics and life-history of these organisms have been investigated with the help of the finest developments of modern technique. It is fitting here to record our acknowledgment to two staining methods—Heidenhain's iron-hæmatoxylin and the Romanowsky stain (including Giemsa's and Leishman's modifications), which have added greatly to our technical resources.

There is time to refer only to certain of the Protozoa which directly affect man. Twenty years ago our knowledge of the few species of Protozoa recorded from the human alimentary canal was defective in two important respects—the systematic characters and the biology of the species—so there was much confusion. Subsequent investigations, and especially those of the last ten years (by Wenyon, Dobell, and others), have cleared up most of the doubtful points, but owing to the difficulties of size and the paucity of characters available, it is by no means easy in practice to distinguish certain of the species. Of the seventeen species now known to occur in the intestine of man, *Entamœba histolytica* has received particular attention. This organism lives as a tissue parasite in the wall of the large intestine, where, as a rule, the damage caused is counterbalanced by the host's regenerative processes. But when the destruction outstrips the regeneration intestinal disturbance results, leading to the condition known as amœbic dysentery. The specific characters and the processes of reproduction and encystment of *E. histolytica* are now well ascertained, and it is realised that in the majority of cases the host is healthy, acting as a "carrier" dangerous to himself, for he may develop into a case of acute dysentery, and to the community—for he is passing in his fæces the encysted stage which is capable of infecting other persons. Whether an infected person will suffer from dysentery or act as a healthy "carrier" apparently depends upon his own susceptibility rather than on any difference in the virulence of different strains of the Entamœba.

In all work with Entamœbæ infecting human beings

there is need for critical determination of the species, for, in addition to *E. histolytica*, a closely similar species, *E. coli*, is a common inhabitant of the intestine. This, however, is a harmless commensal, feeding on bacteria and fragments derived from the host's food. The distinction between the two species rests chiefly upon the characters of the nuclei and of the mature cyst—quadrinucleate in *E. histolytica* and octonucleate in *E. coli*—and considerable care and technical skill are requisite in many cases before a diagnosis can be given. Yet this distinction is definitely necessary in practice, for indiscriminate treatment of persons with Entamœba is indefensible; treatment is only for those with *E. histolytica*; it is useless for those with *coli*, and subjects them needlessly to an unpleasant experience.

A notable result of recent work is the proof that the more common intestinal Protozoa, formerly believed to be restricted to warmer countries, occur indigenously in Britain. This was first established by a group of observers in Liverpool, and has been confirmed and extended by subsequent workers. There is good reason for believing that in Great Britain the incidence of infection with *E. histolytica* is about 7 to 10 per cent., and with *E. coli* about five times as great (Dobell).

The discovery (1903) of Leishmania, the organism of kala azar and of oriental sore, added another to the list of important human pathogenic Protozoa, but the mode of transmission of this flagellate has not yet been proved.

Of the problems presented by the parasitic worms, the most momentous are those associated with Ancylostoma and its near relative Necator, which are prevalent in countries lying between 36° N. and 30° S.—a zone which contains more than half the population of the earth. Heavy infection with Ancylostoma or with Necator produces severe anæmia, and reduces the host's physical and mental efficiency to a serious degree. Until 1898 there was no suggestion that infection was acquired in any other way than by the mouth, but in that year Looss published his first communication on the entry of the larvæ of Ancylostoma through the skin, and in 1903 gave an account of further experiments which proved that dermal infection resulted in the presence of worms in the intestine. At the meeting of the British Association in Cambridge in 1904 Looss demonstrated to a small company his microscopical preparations showing the path of migration of the larvæ. His investigations served to establish the importance of the skin as the chief portal of entry of Ancylostoma, and pointed the way to effective methods of prevention against infection.

Another notable advance in helminthology is the working out of the life-cycle of Schistosoma (Bilharzia)—a genus of trematode worms causing much suffering in Egypt and elsewhere in Africa, as well as in Japan and other parts of the world. These worms when mature live in pairs, a male and female, in the veins of the lower part of the abdomen, especially in the wall of the bladder and of the rectum. The eggs, laid in large numbers by the female worm, provoke inflammatory changes, and cause rupture of the veins of the organs invaded. Until about ten years ago the life-history of Schistosoma had been traced only as far as the hatching of the ciliated larva or miracidium, which takes place shortly after the egg reaches water, but it was then shown that this larva is not, as had been held by Looss, the stage which infects man. Miyairi and Suzuki (1913) found that the miracidium of *Schistosoma japonicum* entered a fresh-water snail which acted as the intermediate host, and Leiper and Atkinson (1915) confirmed and extended this observation, and showed that the miracidia develop into sporocysts in which cercariæ are formed. We owe chiefly to Leiper's work (1915–16) our knowledge of the life-history and method of entry into man of the Egyptian species of Schistosoma. He demonstrated that two species of this parasite occur in Egypt, and established that the miracidia develop in different intermediate hosts: those of *S. mansoni* enter Planorbis, while those of *S. hæmatobium* penetrate into Bullinus—the molluscs being abundant in the irrigation canals. The sporocysts produce cercariæ, which escape from the snails and gather near the surface of the water, and experiments with young mice and rats showed that the cercariæ attach themselves to the skin, enter, and reach the portal system, from which they travel to the veins of the lower part of the abdomen. Infection of man takes place chiefly through the skin when bathing or washing in water containing the cercariæ, though infection may also occur through drinking such water. So, at last, these worms which have troubled Egypt for at least thirty centuries have become known in all their stages, and measures for preventing infection—which were of great use during the War—have been devised, and curative treatment introduced.

Other recent helminthological researches deserve consideration did space permit, for there has been much excellent work on the life-history of the liver-flukes and lung-flukes of man, and the life-cycle of the tape-worm, *Dibothriocephalus latus*, was worked out in 1916–17. Mention should also be made of Stewart's investigations (1916–19) on the life-history of the large round-worm *Ascaris lumbricoides*, during which he made the important discovery that the larvæ on hatching in the intestine penetrate into the wall and are carried in the blood to the liver, and thence through the heart to the lungs, where they escape from the blood-vessels, causing injury to the lungs. The larvæ, now about ten times their original size, migrate by way of the trachea and pharynx to the intestine, where they grow to maturity. During last year Dr. and Mrs. Connal have worked out the life-history of *Filaria* (*Loa*) *loa* in two species of the Tabanid fly, Chrysops, and investigations on other Filarias have thrown light on their structure, but there is still need for further researches on the conditions governing the remarkable periodicity exhibited by the larvæ of some species (*e.g. F. bancrofti*; in some parts of the world the larvæ of this species are, however, non-periodic). The period under review has obviously been one of great activity in research on helminthes, and fertile in measures tending to reduce the risks of infection.

Insects, protozoa, and helminthes not only inflict direct injury on man; they also diminish his material welfare by impairing the health or causing the death of his horses, cattle, and sheep, by destroying food crops during growth, and, in the case of insects, by devouring the harvested grain. The measure of control which man can gain over insects, ticks, and

endoparasitic organisms, will determine largely the extent to which he can use and develop the natural resources of the rich tropical and sub-tropical zone of the earth.

Other applications of zoology to human well-being cannot be dealt with here, but mention should be made of two—the researches on sea-fisheries problems which have formed an important branch of the zoological work of Great Britain for forty years, and the studies on genetics which made possible an explanation of the mode of inheritance of a particular blood-group, and of some of the defects (*e.g.* colour-blindness and hæmophilia) and malformations which appear in the human race.

The Theory of the Affine Field.[1]

By Prof. ALBERT EINSTEIN, For. Mem. R.S.

THE theory of the connexion between gravitation and electromagnetism outlined below is founded on Eddington's idea, published during recent years, of basing "field physics" mathematically on the theory of the affine relation. We shall first briefly consider the entire development of ideas associated with the names Levi-Civita, Weyl, and Eddington.

The general theory of relativity rests formally on the geometry of Riemann, which bases all its conceptions on that of the interval ds between points indefinitely near together, in accordance with the formula[2]

$$ds^2 = g_{\mu\nu} dx_\mu dx_\nu \quad . \quad . \quad . \quad . \quad (1)$$

These magnitudes $g_{\mu\nu}$ determine the behaviour of measuring-rods and clocks with reference to the co-ordinate system, as well as the gravitational field. Thus far we are able to say that, from its foundations, the general theory of relativity explains the gravitational field. In contrast to this, the conceptual foundations of the theory have no relations with the electromagnetic field.

These facts suggest the following question. Is it not possible to generalise the mathematical foundations of the theory in such a way that we can derive from them not only the properties of the gravitational field, but also those of the electromagnetic field?

The possibility of a generalisation of the mathematical foundations resulted from the fact that Levi-Civita pointed out an element in the geometry of Riemann that could be made independent of this geometry, to wit, the "affine relation"; for according to Riemann's geometry every indefinitely small part of the manifold can be represented approximately by a Euclidean one. Thus in this elemental region there exists the idea of parallelism. If we subject a contravariant vector A^σ at the point x_ν to a parallel displacement to the indefinitely adjacent point $x_\nu + \delta x_\nu$, then the resulting vector $A^\sigma + \delta A^\sigma$ is determined by an expression of the form

$$\delta A^\sigma = -\Gamma^\sigma_{\mu\nu} A^\mu \delta x_\nu \quad . \quad . \quad . \quad . \quad (2)$$

The magnitudes Γ are symmetrical in the lower indices, and are expressed in accordance with Riemann geometry by the $g_{\mu\nu}$ and their first derivatives (Christoffel symbols of the second kind). We obtain these expressions by formulating the condition that the length of a contravariant vector formed in accordance with (1) does not change as a result of the parallel displacement.

Levi-Civita has shown that the Riemann tensor of curvature, which is fundamental for the theory of the gravitational field, can be obtained from a geometrical consideration based solely on the law of the affine relation given by (2) above. The manner in which the $\Gamma^\sigma_{\mu\nu}$ are expressible in terms of the $g_{\mu\nu}$ plays no part in this consideration. The behaviour in the case of differential operations of the absolute differential calculus is analogous.

These results naturally lead to a generalisation of Riemann's geometry. Instead of starting off from the metrical relation (1) and deriving from this the coefficients Γ of the affine relation characterised by (2), we proceed from a general affine relation of the type (2) without postulating (1). The search for the mathematical laws which shall correspond to the laws of Nature then resolves itself into the solution of the question: What are the formally most natural conditions that can be imposed upon an affine relation?

The first step in this direction was taken by H. Weyl. His theory is connected with the fact that light rays are simpler structures from the physical view-point than measuring-rods and clocks, and that only the ratios of the $g_{\mu\nu}$ are determined by the law of propagation of light. Accordingly he ascribes objective significance not to the magnitude ds in (1), *i.e.* to the length of a vector, but only to the ratio of the lengths of two vectors (thus also to the angles). Those affine relations are permissible in which the parallel displacement is angularly accurate. In this way a theory was arrived at, in which, along with the determinate (except for a factor) $g_{\mu\nu}$ other four magnitudes ϕ_ν occurred, which Weyl identified with electromagnetic potentials.

Eddington attacked the problem in a more radical manner. He proceeded from an affine relation of the type (2) and sought to characterise this without introducing into the basis of the theory anything derived from (1), *i.e.* from the metric. The metric was to appear as a deduction from the theory. The tensor

$$R_{\mu\nu} = -\frac{\partial \Gamma^\alpha_{\mu\nu}}{\partial x_\alpha} + \Gamma^\alpha_{\mu\beta}\Gamma^\beta_{\nu\alpha} + \frac{\partial \Gamma^\alpha_{\mu\alpha}}{\partial x_\nu} - \Gamma^\alpha_{\mu\nu}\Gamma^\beta_{\alpha\beta} \quad . \quad (3)$$

is symmetrical in the special case of Riemann's geometry. In the general case $R_{\mu\nu}$ is split up into a symmetrical and an "anti-symmetrical" part:

$$R_{\mu\nu} = \gamma_{\mu\nu} + \phi_{\mu\nu} \quad . \quad . \quad . \quad . \quad (4)$$

One is confronted with the possibility of identifying $\gamma_{\mu\nu}$ with the symmetrical tensor of the metrical or gravitational field, and $\phi_{\mu\nu}$ with the antisymmetrical tensor of the electromagnetic field. This was the course taken by Eddington. But his theory remained incomplete, because at first no course possessed of the advantages of simplicity and naturalness presented

[1] Translated by Dr. R. W. Lawson.
[2] In accordance with custom, the signs of summation are omitted.

itself, for the determination of the 40 unknown functions $\Gamma^{\alpha}_{\mu\nu}$. The following brief statement will serve to show how I have endeavoured to fill in this gap.[3]

If the German capital $\mathfrak{H}$ be a scalar density that depends only on the functions $\Gamma^{\alpha}_{\mu\nu}$, then Hamilton's principle

$$\delta\{\int\mathfrak{H}d\tau\}=0 \quad . \quad . \quad . \quad . \quad . \quad (5)$$

supplies us with 40 differential equations for the functions Γ, when we stipulate that during the variation the functions Γ are to be treated as magnitudes independent of each other. Further we assume that $\mathfrak{H}$ depends only on the magnitudes $\gamma_{\mu\nu}$ and $\phi_{\mu\nu}$, and thus write

$$\delta\mathfrak{H}=\mathfrak{g}^{\mu\nu}\delta\gamma_{\mu\nu}+\mathfrak{f}^{\mu\nu}\delta\phi_{\mu\nu} \quad . \quad . \quad . \quad (6)$$

where we have

$$\left.\begin{aligned}\frac{\partial\mathfrak{H}}{\partial\gamma_{\mu\nu}}&=\mathfrak{g}^{\mu\nu}\\ \frac{\partial\mathfrak{H}}{\partial\phi_{\mu\nu}}&=\mathfrak{f}^{\mu\nu}\end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad (7)$$

At this point it should be noticed that in the theory developed here, the small German letters respectively represent the contravariant density ($\mathfrak{g}^{\mu\nu}$) of the metrical tensor, and the contravariant tensor density ($\mathfrak{f}^{\mu\nu}$) of the electromagnetic field. Thus in a well-known manner is given the transition from tensor densities (expressed by German letters) to contravariant and covariant tensors (expressed by the corresponding italic letters), and a metric is introduced which rests exclusively on the affine relation.

By performing the variation we obtain after some amount of calculation

$$\Gamma^{\alpha}_{\mu\nu}=\tfrac{1}{2}g^{\alpha\beta}\left(\frac{\partial g_{\mu\beta}}{\partial x_\nu}+\frac{\partial g_{\nu\beta}}{\partial x_\mu}-\frac{\partial g_{\mu\nu}}{\partial x_\beta}\right)-\tfrac{1}{2}g_{\mu\nu}i^{\alpha}+\tfrac{1}{6}\delta^{\alpha}_{\mu}i_{\nu}+\tfrac{1}{6}\delta^{\alpha}_{\nu}i_{\mu} \quad (8)$$

where

$$\frac{\partial\mathfrak{f}^{\mu\nu}}{\partial x_\nu}=\mathfrak{i}^{\mu} \quad . \quad . \quad . \quad . \quad . \quad . \quad (9)$$

Equation (8) shows that our extension of the theory, which appears to be so general, leads to a structure of the affine relation that does not deviate more strongly from that of the geometry of Riemann than is required by the actual structure of the physical field.

We now obtain the field equations in the following manner. From (3) and (4) we first derive the relations

$$\gamma_{\mu\nu}=-\frac{\partial\Gamma^{\alpha}_{\mu\nu}}{\partial x_\alpha}+\Gamma^{\alpha}_{\mu\beta}\Gamma^{\beta}_{\nu\alpha}+\tfrac{1}{2}\left(\frac{\partial\Gamma^{\alpha}_{\mu\alpha}}{\partial x_\nu}+\frac{\partial\Gamma^{\alpha}_{\nu\alpha}}{\partial x_\mu}\right)-\Gamma^{\alpha}_{\mu\nu}\Gamma^{\beta}_{\alpha\beta} \quad (10)$$

$$\phi_{\mu\nu}=\tfrac{1}{2}\left(\frac{\partial\Gamma^{\alpha}_{\mu\alpha}}{\partial x_\nu}-\frac{\partial\Gamma^{\alpha}_{\nu\alpha}}{\partial x_\mu}\right) \quad . \quad . \quad . \quad . \quad (11)$$

In these equations the $\Gamma^{\alpha}_{\mu\nu}$ on the right-hand side are to be expressed by means of (8) in terms of the $\mathfrak{g}^{\mu\nu}$ and $\mathfrak{f}^{\mu\nu}$. Moreover, if $\mathfrak{H}$ is known, then on the basis of (7) $\gamma_{\mu\nu}$ and $\phi_{\mu\nu}$, *i.e.* the left-hand sides of (10) and (11), can also be expressed in terms of $\mathfrak{g}^{\mu\nu}$ and $\mathfrak{f}^{\mu\nu}$. This latter calculation can be simplified by means of the following artifice. Equation (6) is equivalent to the statement that

$$\delta\mathfrak{H}^{*}=\gamma_{\mu\nu}\delta\mathfrak{g}^{\mu\nu}+\phi_{\mu\nu}\delta\mathfrak{f}^{\mu\nu} \quad . \quad . \quad . \quad (6a)$$

is also a complete differential, so that if $\mathfrak{H}^{*}$ is an unknown function of the $\mathfrak{g}^{\mu\nu}$ and $\mathfrak{f}^{\mu\nu}$, the following relations will hold:

$$\left.\begin{aligned}\gamma_{\mu\nu}&=\frac{\partial\mathfrak{H}^{*}}{\partial\mathfrak{g}^{\mu\nu}}\\ \phi_{\mu\nu}&=\frac{\partial\mathfrak{H}^{*}}{\partial\mathfrak{f}^{\mu\nu}}\end{aligned}\right\} \quad . \quad . \quad . \quad . \quad . \quad (7a)$$

We now have only to assume $\mathfrak{H}^{*}$. The simplest possibility is obviously

$$\mathfrak{H}^{*}=-\frac{\beta}{2}f_{\mu\nu}\mathfrak{f}^{\mu\nu} \quad . \quad . \quad . \quad . \quad (12)$$

In this connexion it is interesting that this function does not consist of several summation terms which are logically independent of each other, as was the case with the theories hitherto proposed.

In this way we arrive at the field equations

$$R_{\mu\nu}=-\kappa[(\tfrac{1}{4}g_{\mu\nu}f_{\sigma\tau}f^{\sigma\tau}-f_{\mu\sigma}f^{\sigma}_{\nu})+\gamma f_{\mu}f_{\nu}] \quad . \quad (13)$$

whereby $R_{\mu\nu}$ is the Riemann tensor of curvature. κ and γ are constants, f_μ is the electromagnetic potential, which is connected with the field strength by the relation

$$f_{\mu\nu}=\frac{\partial f_\mu}{\partial x_\nu}-\frac{\partial f_\nu}{\partial x_\mu} \quad . \quad . \quad . \quad . \quad . \quad (14)$$

and with the electrical current density by the relation

$$\mathfrak{i}^{\mu}=-\gamma\mathfrak{g}^{\mu\sigma}f_{\sigma} \quad . \quad . \quad . \quad . \quad . \quad (15)$$

In order that these equations may be in accord with experience, the constant γ must be practically indefinitely small, for otherwise no fields would be possible without noticeable electrical densities.

The theory supplies us, in a natural manner, with the hitherto known laws of the gravitational field and of the electromagnetic field, as well as with a connexion as regards their nature of the two kinds of field; but it brings us no enlightenment on the structure of electrons.

[3] Herr Droste of Leyden hit upon the same idea independently of the present writer.

Further Determinations of the Constitution of the Elements by the Method of Accelerated Anode Rays.[1]

By Dr. F. W. ASTON, F.R.S.

BY further use of the method of accelerated anode rays, results have been obtained with a number of elements since the publication of the isotopes of copper (NATURE, Aug. 4, p. 162). Details of the method will be published later. Most of the following results were obtained by the use of fluorine compounds of the elements investigated.

The mass-spectrum of strontium shows one line only, at 88. This was obtained in considerable intensity. If any other constituents exist they must be present

[1] A paper read on September 18 before Section A of the British Association Meeting at Liverpool.

in very small quantities, so that it is practically certain that the chemical atomic weight 87·63 at present in use is too low.

Cobalt also appears to be a simple element of mass-number 59, as was to be expected from its atomic weight, which has been determined with great care by a number of observers.

Scandium was successfully attacked by the use of material kindly supplied by Prof. Urbain, of Paris. The only line obtained was at 45. It may be taken provisionally to be a simple element, but the effects are not strong enough to disprove the presence of small quantities of another constituent.

Manganese behaved surprisingly well, and yielded unequivocal results indicating that it is a simple element of mass-number 55. This result is in good agreement with the chemical atomic weight, and is particularly interesting, for 55 is a term in the numerical series 2, 3, 5, 8, 13—all of which had previously corresponded to gaps in the list of weights of known species of atoms.

Gallium fluoride made from a specimen of the hydrate kindly provided by Prof. Richards, of Harvard University, also gave satisfactory results. Gallium consists of two isotopes, 69 and 71. The intensity relation between the lines agrees much better with the atomic weight 69·72 recently published by Richards than that previously in use, 70·1.

Vanadium and chromium give single mass-lines at positions expected from their atomic weights 51 and 52.

Titanium gives a strong line at 48. On one of the spectra obtained there is a faint and doubtful indication of a line at 50. Should this latter be confirmed it would tend to support Honigschmid's value 48·1 for the atomic weight rather than the lower figure 47·85 more recently obtained by Baxter.

Silver in the form of the chloride worked unexpectedly well, and gave two nearly equally intense lines at 107, 109.

Yttrium gives a single strong line at 89, another term of the numerical series already referred to, and completes the analysis of the first 39 elements.

A specimen of potassium hafnifluoride sent from Copenhagen by Dr. Hevesy was experimented with, but in no case were any lines visible in the region of the expected atomic weight of hafnium. This sample contained about 50 per cent. of zirconium, and an extremely faint effect at 90 shown here and on other plates taken with pure zirconium salts suggests this as the principal isotope of this element; but further work is necessary on this point.

Niobium, molybdenum, cadmium, barium, and lead have all been tried without any definite results, and it is feared that difficulties may arise in finding suitable compounds to use in the case of these and other elements not yet analysed. On the other hand, success with scandium and yttrium offers hope of obtaining the mass-spectra of all the rare-earth group.

The following is a list of the elements the composition of which has been first indicated by the use of accelerated anode rays. The mass-numbers were usually determined with reference to the lines of iron or iodine, and no outstanding divergence from the whole-number rule was observed.

Element.	Atomic Number.	Atomic Weight.	Minimum Number of Isotopes.	Mass-numbers in Order of Intensity.
Sc	21	45·1	1	45
Ti	22	48·1	1	48
V	23	51·0	1	51

Obituary.

Sir Henry Hubert Hayden, F.R.S.

ALL who knew Sir Henry Hayden well enough must recall a passing thought, more than once definitely formulated, that some day his irrepressible keenness for exploring new and little-known lands would lead to accident. Those who had the inestimable privilege of knowing him with real intimacy know well that, if he had to choose a way of ending his career, it would be on a mountain side and in a fight against physical difficulties. He never revealed and probably never entertained but one fear—that the medical history of his family might repeat itself and render him unfit for further exploratory work. It is appropriate that he should be laid to rest near the foot of a great mountain, and appropriate too that it should be the mountain which he had just conquered, for as a mountaineer he was as efficient as he was daring.

To accomplish a difficult task in exploration was in itself his sufficient reward. Kindred spirits and but very few others knew of his accomplishments; for, without being reticent, he never looked to the "gallery": his photographs, maps, sketches, and collections were made readily available to specialists, but rarely, and only under pressure, were they turned into lantern slides. The end of one task was to him the beginning of the next: there never was an interval for popular demonstrations, and little even for rest.

Each geographical enterprise was invariably in a new field, and Hayden's geological work was just as varied — geotectonic problems in the Himalayas, economic mineral questions in various parts of India, pure palæontology, the application of geology to engineering problems, and the microscopic petrology of igneous rocks formed the subjects of his papers, each treated in turn with a thoroughness and sense of relativity that revealed a wide and precise acquaintance with literature, which was always surprising to those who were impressed by his restless physical activity in the field.

Since January 3, 1895, when I met Hayden on his landing at Calcutta to join the Geological Survey of India, I have been in closer and perhaps more constant touch with him than most of his friends, and during those twenty-eight years I never heard from him an ungenerous remark about a colleague, never heard him grumble about the climate, at the work, or even at the inequalities of treatment that seem to be the

inevitable characteristic of every form of official service. Two examples are worth recording, for every friend of Hayden will recognise them as typical.

We were moving camp to a new field where there was a probability that the fast-coming hot weather would soon make work difficult. The hot, west winds, laden with fine dust, had significantly started as a warning that life in tents would soon be impossible. Every day was important, when, through the negligence of a local subordinate official, transport facilities broke down absolutely within twenty miles of our new field. I was annoyed especially because my mail having been directed from headquarters to the new camp, the enforced halt could not be utilised even for office work. There seemed to be no escape from a wasted day of useless grumbling. On rising next morning Hayden was missing, but by noon he turned up loaded with heavy postal packets, and then I found that he had been to fetch my mail, and, as I afterwards discovered, had cycled nearly forty miles over what only an Indian District Board would be content to call a road. Few but Hayden would have thought of it; none but Hayden would have done it silently, as if it were only the usual thing.

Four years later Sir Francis Younghusband was starting on his mission to Lhassa. The remarks in the Director's Annual Report for 1902–3 (Rec. Geol. Surv. Ind., vol. xxxii. pp. 153-156) show why at that time we were anxious to know whether on the northern side of the snow-covered, crystalline range of the Eastern Himalaya there had been an extension of the Mesozoic fossiliferous basin which had been surveyed in Spiti and other parts of the north-western Himalaya. I hurried to Darjeeling to intercept Younghusband, who was then on his way to join the expedition that had already started into Sikkim. He realised the value of the problem and readily offered to give facilities for a geologist to join the party, but warned me that unless an officer could move at once he might be too late. I returned immediately to Calcutta and put the question before Hayden, who promptly volunteered to cancel his local engagements, and although he knew the meaning of winter on the inhospitable plateau of Tibet, did not wait to discuss conditions or settle his local affairs, but moved off within twenty-four hours, trusting to pick up transport and equipment on the way. Within a fortnight there came back a parcel of Spiti shale fossils and a letter that opened a new chapter in Himalayan geology. Hayden was away for more than a year, and how he covered so much ground with such excellent results was known only to him and to his kindred spirit, Sir Francis Younghusband.

Always moving rapidly, but never too hurried to help a colleague; always doing something, but mentally as well as physically, Hayden piled up a record of solid results which would have been the envy in turn of the sportsman, the explorer, the scientific worker and the most orthodox official. After graduating at Trinity College, Dublin, in engineering as well as arts, he made a journey round the world before joining the Geological Survey of India in 1895. He was appointed Director of the Department in 1910 and held office for eleven years. Meanwhile, as a junior officer his work touched most of the provinces of India, but his Himalayan and trans-frontier stratigraphical work naturally attracted most attention, the chief scientific results being included in his memoirs on Spiti and Bashahr (Mem. Geol. Surv. Ind., vol. xxxvi., part 1), on the provinces of Tsang and Ü in Central Tibet (vol. xxxvi., part 2), and on Northern Afghanistan (vol. xxxix., part 1). Just before leaving for Switzerland he completed and sent to the press in French his account of the journey through northern Tibet during 1922, that is, after he had retired from the Indian Government service.

In 1915 the Geological Society awarded Hayden the Bigsby medal, and he was elected a fellow of the Royal Society in the same year, whilst Calcutta University conferred on him the honorary degree of D.Sc. He served successively as president of the Mining and Geological Institute of India and of the Asiatic Society of Bengal. In 1911 his official service was recognised by the C.I.E.; in 1919 he received the senior order of C.S.I., and on the day of his embarkation at Bombay in June 1920, preparatory to retirement from the office of Director of the Geological Survey, his knighthood was gazetted.

The accident which led to Hayden's death with his two guides must have occurred soon after August 12, on his return from an ascent of the Finsteraarhorn, but his body was not found until August 28. The details of his death will never be known, but if the final and determining incident was not a definite attempt to save his companions, it was not Hayden's fault. He was buried by friends on September 1 at Lauterbrunnen, and the selection of the spot would almost certainly be in accordance with his own wish. Perhaps of all the many incidents that one can recall as illustrations of his generous nature, my last glimpse of him was the most characteristic: it was just a few days before he started on his tour in Switzerland; he was busy with his preparations, but looked in to say farewell on his way to see the sick relative of a friend who was away from home. One frequently came across instances of his generosity to the poor and sick, but not even the most intimate of his friends knew them all; as in his work, each act of kindness followed too closely on its predecessor to allow of time for talking about it.

T. H. HOLLAND.

THE issue of the *Physikalische Zeitschrift* for July 15 contains an obituary notice of Prof. O. Lehmann by Drs. A. Schleiermacher and K. Schachenmeier. He was born on January 13, 1855, at Constance, where his father, F. X. Lehmann, was director of the training college. As an only child he spent much time in his father's laboratory and was interested in his search for mathematical law in organic life. He studied under Kundt and Groth at Strasbourg, and after graduating taught in schools in Baden and Alsace until 1883, when he became lecturer and afterwards extra professor at the polytechnic at Aix-la-Chapelle. After a year as extra professor at Dresden he succeeded Hertz as director of the physics department of the technical school at Carlsruhe in 1889. He took a prominent part in the meetings of the scientific society of Carlsruhe and was noted for the experiments with which he illustrated his lectures. He is best known in Great Britain for his work on liquid crystals and for the improvements he made to the microscope to facilitate that work. His death occurred on June 17, 1922, some time after his retirement.

Current Topics and Events.

THE ninety-first annual meeting of the British Association, which closed at Liverpool on Wednesday, September 19, was one of the most successful in the history of the Association, and all who have been concerned in the arrangements for it, whether local or sectional, are to be congratulated upon the gratifying result of their work. More than three thousand members attended the meeting, and the facilities afforded them for social amenities and scientific discussion were much appreciated by all. As nominated by the Council, Sir David Bruce was elected by the General Committee as president for the meeting to be held in Toronto on September 3-10 of next year. The Committee also cordially accepted the invitation from Southampton to meet there in 1925. On Monday, September 17, the honorary degree of doctor of science of the University of Liverpool was conferred upon the following distinguished men of science: Sir Ernest Rutherford; Prof. Niels Bohr, professor of physics in the University of Copenhagen; Dr. E. H. Griffiths; Prof. G. N. Lewis, professor of chemistry, University of California; Prof. G. Elliot Smith, professor of anatomy in University College, London; Dr. Johs. Schmidt, director of the Carlsberg Laboratory, Copenhagen; and Prof. J. C. McLennan, professor of physics in the University of Toronto.

CANON BARNES of Westminster preached the sermon on Sunday last in the Lady Chapel of Liverpool Cathedral on the occasion of the British Association's visit to that city. He dealt with "The Influence of Science on Christianity," and with characteristic courage attributed the waning influence of the churches to the obscurantism and static outlook of many exponents of religion. Christianity has gained much from progress external to itself; the pronounced ethical progress in the Roman Empire in the second century was a wide movement for which religion cannot claim the whole credit; thirteen centuries later the Renaissance had an invigorating effect, producing in the churches changes destined to be as permanent and valuable as they were extensive: the pity was that in the nineteenth century the churches did not take advantage of the changes produced in the outlook of educated men by the scientific movement, but, led by the tractarians, adopted rather an attitude of hostility which has resulted in the modern conflict of ideas among clerics themselves, and has prejudiced educated people against their teachings. "Faith is a necessity of existence. Zealots still contend that there is a moral value in blind faith. But the modern world, so far as it has fallen under the sway of the scientific method, demands that faith shall be reasonable and not blind." Inability to grasp new ideas, reluctance to discard or even to modify theories or beliefs, are qualities perhaps more rare among scientific workers than among theologians; but we are too accustomed to the conservatism of outlook among the former, particularly those whose life-work has been in the direction of elaboration of what are to them fundamental principles amounting to beliefs, to fail to appreciate the magnitude and importance of the task of the best contemporary theologians in combating religious obscurantism.

IF the first accounts exaggerated the number of lives lost, the latest figures reveal the completeness of the disaster caused in Japan by the earthquake of September 1. Although the exact number of deaths caused by earthquake and fire is still unknown, it is estimated that, approximately, 110,000 were killed in Tokyo, 30,000 in Yokohama, 10,000 in Kamakura, 10,000 in the Miura Peninsula, 700 in Odowara and Atami, and 5000 in the Boso Peninsula—a total of 165,700. In Yokohama, about 71,000 houses were destroyed and about 100 escaped damage; in Yokosuka, all but 150 out of 11,800 houses were destroyed; in Tokyo, 93 per cent. of the houses were burnt or crushed. Most of the high concrete buildings damaged in Tokyo show fissures in the third-floor façades, but above and below that floor there is little injury. The fire destroyed a great part of the Imperial University, including 700,000 volumes in the library. At first, the shock at Yokohama was not severe and differed little from those so often felt in Japan. Then, suddenly, there came a swirling motion (the vorticose shock of the Italians), during which practically all houses collapsed instantaneously. Several early reports with regard to the effects of the shock prove to have been erroneous. There was no volcanic eruption in the island of Oshima and none of the islands off the Izu Peninsula disappeared. Dr. Nakamura has made a preliminary investigation of the central area. He finds that the earthquake originated in two separate foci, one between Oshima and Atami, in which the first and more violent movement seems to have originated, the other near the naval station of Yokosuka.

THE Howard silver medal for 1923 of the Royal Meteorological Society has been awarded to Cadet J. C. Needham of H.M.S. *Worcester* for the best essay on "Tropical Storms." The medal was competed for by the cadets from H.M.S. *Worcester*, H.M.S. *Conway*, and the Nautical College, Pangbourne.

THE International Commission of Eugenics met at Lund in Sweden on September 1 and 3 under the chairmanship of Major Leonard Darwin. Various resolutions were passed, and the question where the next international congress should be held was discussed. Profs. Nilsson-Ehle and Johansson were appointed members of the Commission. The Commission was entertained at dinner by the Mendelian Society and visited the Swedish Institute of Genetics at Akarp near Lund, and the Swedish State institute for race biological investigation. These are the only institutions in the world for genetics or eugenics which are State-endowed.

"HEALTH WEEK" is to be celebrated on October 7–13. This movement was instituted in 1912 and the arrangements are made by a committee appointed by the Royal Sanitary Institute, 90 Buckingham Palace Road, S.W.1. The object of Health Week

is to focus public attention for one week in the year on matters of health, and to arouse that personal responsibility for health, without which all public work, whether by Government or by Local Authorities, must fall far short of its aims. It is suggested that the dominant idea should be "Self Help in Health," and the consideration of what every individual can do for himself and his neighbour in securing a healthy life. While there is this central Health Week Committee, local celebrations in each centre are organised and controlled by local committees, and a circular has been issued for the formation and guidance of the latter, containing suggestions for the programme of events and subjects for lectures. The Health Week Committee is working in cordial co-operation with the National Baby Week Council (already referred to in these columns), and it has been found convenient in several instances to combine the celebrations of Health Week and Baby Week.

An Empire Mining and Metallurgical Congress is to be held at the British Empire Exhibition in London during the first week in June 1924. The Institution of Mining and Metallurgy, the Institution of Mining Engineers, the Institution of Petroleum Technologists, the Iron and Steel Institute and the Institute of Metals, representing the scientific and technical interests of the mineral and metal industries, with the Mining Association of Great Britain and the National Federation of Iron and Steel Manufacturers, are co-operating as conveners of the Congress. This is the first such Congress to be held, and it is anticipated that succeeding sessions will be held in the Dominions under the auspices of an Empire Council of Mining and Metallurgical Engineering Institutions, which it is hoped will be constituted as a result of the inaugural Congress. Viscount Long of Wraxall will deliver the Sir Julius Wernher Memorial Lecture of the Institution of Mining and Metallurgy at the opening session of the Congress, taking mineral resources and their relation to the prosperity and development of the Empire as his subject. The May Lecture of the Institute of Metals to be delivered by Dr. F. W. Aston, on "Atoms and Isotopes," will also form part of the programme of the Congress.

An unusual insurance claim is recorded by the New York correspondent of the *Times* in a message dated September 13. The University of Indiana took out a policy at a cost of about 30*l.* to insure against possible failure of the party from the University sent to Ensenada, Mexico, to take good photographs of the total solar eclipse of September 10. The expedition was unsuccessful, and the insurance company duly paid out about 300*l.*, which is to go towards the cost of the expedition. A similar insurance policy, but for 2000*l.*, was taken out by the Swarthmore College party, which was also in Mexico. The compensation in this case was to be inversely as the success of the expedition in obtaining photographs. It is stated that good photographs of the solar corona were obtained.

Up to July 2, no less than 826 broadcasting stations had been licensed in the United States. For various reasons, however, chiefly financial, 376 of them have ceased to operate. Nearly half the total number of working stations are run by radio and electrical companies. The rest are run by newspapers, stores, colleges, churches, etc. That the art of broadcasting has come to stay is proved by the fact that only a small percentage of the stations were discontinued because their service was unsatisfactory to the public. In a few cases stations were closed down because of the competition of neighbouring rival stations. In Great Britain there is only a single organisation for broadcasting, and so the public does not get the benefit of improved service owing to competition. On the other hand, however, it is imperative that the industry be in a sound financial position if it is to work satisfactorily.

A memorandum on the rainfall in India during June and July and the probable amount during August and September has recently been issued by the Indian Meteorological Department. The monsoon was late in arriving on the shores of India, and was weak throughout the month of June. There was a general strengthening of the monsoon currents in the early part of July, and during the month well-distributed rain fell over most of India. For the two months of June and July the rainfall over the plains of India was about 6 per cent. above normal. The excess was large in Lower Burma and in the North-West Frontier Province and Rajputana West. The amount was short of the normal by more than 20 per cent. in most of the Madras Presidency, Orissa, the East Central Provinces, Berar, the West United Provinces, and mostly along the western frontier. The forecast issued in the early part of August states that there is no reason to expect any large departure from the normal in the rainfall of India generally in August and September. Reports received from India by the India Office show for the mid-week in September that there was an excess of rain in west Central India, north Hyderabad, and south-east Madras; normal amounts in Lower Burma, Orissa, west Central Provinces, and north Madras; elsewhere rains were scanty.

Prof. A. R. Forsyth recently delivered a lecture on the life and work of Sir Isaac Newton, under the auspices of the London County Council, and it is published as an article in the *Empire Review* for September. This is an opportune moment to refresh the public memory on Newton's life and achievement, when so much interest is being taken in Einstein's modification of the Newtonian law of gravitation. In addition to a biographical sketch, the article gives a summary of the state of mathematics and astronomy when Newton was at Cambridge, and the preparatory work done by Copernicus, Tycho Brahé, Kepler, and Galileo in leading up to the Principia. It is explained that the geometrical methods of the Principia were adopted, because the validity of the infinitesimal method, which Newton had himself employed, was still a matter of controversy. Comment is made on the curious fact that Newton took a degree of the earth's circumference as 60 miles in his first abortive

test of his law; the correct value had been published in England thirty years earlier by Richard Norwood. The fact that international jealousy delayed the universal acceptance of the law of gravitation seems strange to us now; there is, however, a slight echo of it in the antipathy shown to Einstein in some quarters, because of his nationality. The article shows the important part that Voltaire played in persuading the French of the truth of Newton's law. Thus we find that before the return of Halley's comet in 1759, Clairaut and Lalande calculated its perturbations by gravitational methods. Prof. Forsyth makes the practical suggestion that the bicentenary of Newton's death in 1927 should be marked by a new edition of his collected works. There has been none since Horsley's edition in 1785, and many additional manuscripts have been discovered since that date.

THE Almanac for the year 1923 published by the Egyptian Government contains, in addition to the usual statistical information, a good deal of matter of scientific interest. There are chapters on the geographical features, and special attention is given to the Nile. Agriculture and antiquities receive considerable attention, and there is a long section on irrigation. It is noted that the almanac is intended to be explanatory and descriptive rather than statistical, and in this respect is intended to supplement the "Annuaire Statistique." The book is a valuable volume of reference on Egypt.

Our Astronomical Column.

A LARGE FIREBALL.—Mr. W. F. Denning writes: "On September 7, at 7.45 P.M., G.M.T., a large fireball was observed from many places in the south-west of England. As viewed from Par, Cornwall, it appeared as large as the full moon, and passed from the west over north-west, and finally disappeared in north-north-west. It left a brilliant trail of light, and this remained conspicuously obvious to the unaided eye during five minutes. The trail exhibited some singular changes of shape and position while it continued in sight. It first assumed a vertical direction, after which the extremities curved to the left and formed a semi-circle.

"A number of other observers in Cornwall have reported observations of the phenomenon, and among other places it appears to have been well observed at Fowey, Liskeard, and Polruan. The object was also seen from Southampton, from which place the enduring streak was situated due west at an altitude of 16°."

STELLAR MASSES.—Accumulating statistics on binary systems, combined with the great increase in the number of fairly trustworthy parallaxes, have made it possible to deduce mean values of the stellar masses for each spectral type. Messrs. Russell, Adams, and Joy investigate the matter in a joint paper in Pub. Ast. Soc. Pacific for August, using about 400 stars. They assign to type O masses of 6 to 9, to type B mass 6, to giants of types A to G masses 2 to 4, and to the dwarfs of all classes masses ½ to 2½; in each case the unit is the sun's mass.

On plotting mass against absolute magnitude, they obtain a graph that is practically a straight line, though with a slight upward bend for type B. This result seems to lead to a fairly obvious corollary, which is not, however, given by the authors. It is that the duration of the stellar universe in the past is of the same order as that of the luminous period of individual stars. If it were much greater than this, then even the most massive stars would have had time to distribute themselves among all the ranks of absolute magnitude. The same conclusion is obtained by dynamical studies of the stellar motions, which do not indicate any great preponderance of non-luminous stars.

The recently published report of the Cape Observatory states that the stellar masses are also being investigated there. The results suggest that the masses group themselves about certain standard values, 11½, 5¾, 2⅞, 1¼ of the sun, each being about double the following. If this law should be established, it would indicate that the large masses were determined by some physical cause, and that they were liable to successive subdivision into equal parts.

HEAT RADIATIONS OF PLANETS.—Allusion has already been made in these notes to the investigation by Messrs. Edison Pettit and Seth Nicholson on the dark heat-waves emitted by the planets. These are isolated by the use of a cover-glass transmitting between 0·3 μ and 5·5 μ (with a weak extension to 7·5 μ), and a water-cell transmitting between 0·3 μ and 1·3 μ. The curve of atmospheric transmission at Mt. Wilson is a very complicated one, with eight minima between 0 and 8 μ, and two maxima between 8 μ and 14 μ. The dark planetary radiations are chiefly in the latter region. The deflexion from the planet Mercury has been compared with that from the moon, the ratio of radiation per unit area being 264/206, a smaller ratio than would be expected in view of Mercury's proximity to the sun. The authors make the suggestion that it may indicate a rapid rotation of Mercury; they note in corroboration of this that they obtain a sensible deflexion even from the dark portion of Mercury's disc.

Their former measures indicated practically no dark heat from Jupiter, but the present series gives 78·1 per cent. of its radiation between 0·3 μ and 1·3 μ, 15·3 per cent. between 1·3 μ and 5·5 μ, and 6·6 per cent. between 8 μ and 14 μ.

A SMALL STELLAR MASS.—*Astr. Nachr.*, No. 5246, contains an investigation of the orbit of the binary O. Struve 400, by P. Meier. The position for 1900 is R.A. $20^h\ 6^m\ 54^s$, N. Decl. 43° 39′, magnitude 7·7, spectral type G 3; trigonometrical parallax 0·043″ (Sproul Observatory), spectroscopic parallax 0·030″ (Mt. Wilson). The elements obtained are: period 84·4 years, periastron 1885·1, e 0·48, ω 19·4°, Ω 143·9°, i 62·5°, a 0·428″. The observations used extend from 1843 to 1922, so that practically a revolution has been completed. Using the Sproul parallax, the sum of the masses is 0·138 of the sun. (By a slip this is printed in *Astr. Nachr.* as 0·014 of the sun.)

The smallest stellar mass hitherto measured is that of the faint component of Krüger 60, which is about one-seventh of the sun; but if the present result is trustworthy, the joint mass of the pair is equal to that of this star.

A comparison of observed and computed positions is given. The agreement is fair, considering the closeness of the pair. The star is one that should be kept under observation. The components are furthest apart, 0·62″, in 1932; the separation is more than 0·50″ till 1948.

Research Items.

The Horse in Babylonia.—In the June issue of the Philadelphia *Museum Journal* Mr. Leon Legrain describes a series of Babylonian seals in the museum collection. In one of the most remarkable the rider, whip in hand, is represented with a bird-like head in profile with no distinct hair or beard, mounted on an animal which may be a horse or a donkey. Mr. Legrain is half disposed to regard this as the first representation of the horse in Babylonia, but this is far from certain. In the only known example of this type the animal has been called a bull, and the rider identified with the thunder god, Ramman Adad. But as the seal probably dates from the time of the Guti invasion, this mode of riding astride may be a new and foreign feature imported from the north-east by the Guti people.

Effect of Drying upon the Skull.—In an interesting paper in the *Journal of Anatomy* (vol. lvii., pt. iv., July 1923), T. Wingate Todd discusses the effect of maceration and drying upon the linear dimensions of the green human skull. His observations cover the effects of drying upon twenty-four macerated skulls and the differences between eight green skulls and the same within twelve hours of emergence from the macerator. He concludes that great individual variation occurs in percentage shrinkage, which, relatively small for length, increases somewhat for breadth and height, upon transformation from the green to the dry macerated state. The average shrinkage (all dimensions) amounts to about 1·1 per cent. of the final measurement. The duration of measurable shrinkage is about three weeks; but shrinkage demonstrable by shifting of the Euryon may continue for three months. Sex, stock, age, cranial thickness, cranial shape, and the condition of sutures are all eliminated as factors having no influence upon shrinkage. In passing through the stage of maceration, and during the first few hours of drying, the green skull loses a total average of 0·84 mm. in length, breadth, and auricular height. The average total shrinkage in complete transformation from the green to the dry macerated state is given as 5·6 mm., corresponding to a reduction of about 42 c.c. in a cranium of some 1500 c.c. capacity. The writer further gives examples showing that, given the linear dimensions in green and dry macerated states, it is possible to calculate the shrinkage in capacity to within a few cubic centimetres by either the Cleveland formula or those of Lee and Pearson.

Bird Censuses in the United States.—The United States Department of Agriculture has just published, as Bulletin No. 1165, a "Report on Bird Censuses in the United States: 1916 to 1920," by May Thatcher Cooke, of the Bureau of Biological Survey. The paper deals with an interesting attempt to establish a statistical basis for the study of the problems of bird population—the numbers and distribution of birds of different species, annual and other fluctuations, and the effects of irrigation, of cultivation, of the clearing of woodlands, and of protective legislation. The subject is one both of scientific interest and of economic importance: the study of it is not unknown in Great Britain, but it has not so far been undertaken on an important scale. A census takes the form of an annual count of the number of breeding pairs on a defined tract of land which is taken to be representative of the district as a whole. The conclusions so far reached in America, as mentioned in the paper under notice, are purely tentative, and only a part of the United States is adequately covered by the records for the period. For the section of the country lying north of Maryland and the Ohio River and east of the Great Plains, a little more than one pair of birds to the acre is found to be the present average for farm land. For the land immediately surrounding the farm buildings, and including lawns and orchard, the average is about 130 pairs per 100 acres, the estimated population of an entire farm of 100 acres being about 112 pairs. The American robin (*Turdus migratorius*) is the most abundant species in those States lying north of North Carolina and east of the Mississippi, and the alien house-sparrow (*Passer domesticus*) takes second place: for farm land in this section there are about 9 pairs of robins and 8 pairs of sparrows per 100 acres. Further and more comprehensive figures should make interesting comparisons possible.

The Opalinid Ciliate Infusorians.—Dr. M. M. Metcalf has recently published (U.S. Nat. Mus., Bull. 120) what he describes as a preliminary review—a memoir of 484 pp., with 258 illustrations—of these ciliates which live in the rudimentary cæcal portion of the rectum of Anurid amphibia. Most of the material used in the study of the 150 new species, sub-species, and formæ was obtained from museum specimens of Anura which had lain long—some for more than eighty years—in alcohol. The author gives a general account of the structure and life-history of *Protoopalina intestinalis*—a binucleate opalinid—and deals in some detail with mitosis and other nuclear phenomena in this and other forms. He concludes that each ordinary nucleus of an opalinid contains both trophic and reproductive chromatin in full activity. Dr. Metcalf discusses the relationships (*a*) of the four genera—Protoopalina, Zelleriella, Cepedea, and Opalina, and (*b*) of the family. He suggests that the Opalinidæ and Trichonympha may have arisen from similar ancestors, and that still more probably the Euciliata arose from ancestors which had become disturbed in their relations of mitosis and fission, and that they had passed through a pseudobinucleate condition to one of true binucleation, finally reaching their present structure, having two nuclei—one hypertrophied for metabolism, the other inactive except during the sexual period. An important section of the memoir deals with the geographical distribution of the species of Opalinidæ and the families and sub-families of the Anura.

Skin Spot of Potatoes.—Skin spot has frequently been regarded as a relatively unimportant blemish upon the potato tuber, so that considerable interest was aroused by the recent announcement by Shapovalov (*Journ. of Agricultural Research*, vol. 23, pp. 285-294) that the pustules of this disease represent a primary stage of corky scab, a much more serious trouble produced by *Spongospora subterranea*. Until this paper, it had been generally assumed on the basis of a paper by Miss M. N. Owen (*Kew Bulletin*, 1919, pp. 289-301) that skin spot was due to quite a different organism, a new species of Oospora, named by the discoverer *O. pustulans* Owen and Wakef. As skin spot frequently occurs upon seed tubers of many of the best-known varieties of potatoes, it was obviously of great importance to know whether the organism causing skin spot could also give rise to corky scab, and potato-growers will read with relief the communication by W. A. Millard and Sydney Burr in *Kew Bulletin*, No. 8 for 1923. This work

records the results of inoculation experiments with both *Oospora pustulans* and *Spongospora subterranea*, which confirm Owen's original conclusions completely, and leave no doubt that the first organism is responsible for skin spot and the second for corky scab. Anatomical investigations of the pustules also show clear differences between those of skin spot and of corky scab, and there is no likelihood of a skin spot pustule later masquerading as a typical corky scab. Shapovalov's contrary results were obtained in the United States, and Millard and Burr are therefore led to make the suggestion, inevitably suggested by their own work, that except when the American author examined diseased tubers sent from Europe, he never had typical skin spot under observation.

VARIATIONS IN LEVEL OF LAKE VICTORIA NYANZA.—Attention was directed in 1904 to the remarkable variations in the level of the Victoria Nyanza by Col. Lyons, who attributed some of them to differential movements in the adjacent land. The general oscillation of the level in that lake and in the Albert Nyanza is described by Mr. C. E. P. Brooks in a Geophysical Memoir, No. 20, issued by the Meteorological Office (1923; 8 pp., 1 pl.; price, 1*s.* 6*d.*). Mr. Brooks describes the variations in the lake levels as recorded by tide gauges on the Victoria Nyanza from 1896 to 1922 and on the Albert Nyanza from 1904 to 1922, and compares the rise and fall of the lakes with the variations in sunspots and rainfall. The discharge from the Victoria Nyanza over the Ripon Falls is estimated at only 6 per cent. of the rainfall on the basin of the lake. Most of the rain is removed from the basin by evaporation, which Mr. Brooks regards as highest during periods of sunspot minima, so that the lake level is then normally lowest. He claims that the lake levels accord more closely with variations of sunspots than with those of rainfall. He points out in illustration of this view that the great rise in the level of the two lakes in 1917 was "entirely unconnected with any increase in the rainfall." The curves on the plate illustrating the memoir show a general agreement of the sunspot minima with the lake levels: but the agreement is not complete, for the sudden rise in 1901 followed an increase in rainfall but without any equivalent movement in the sunspot curve. There was a similar disagreement in 1913, and moreover, the high level of the Victoria Nyanza in 1906 preceded instead of followed the sunspot maximum of 1907.

SPACE FORMULÆ OF BENZENE, NAPHTHALENE, AND ANTHRACENE.—The carbon atoms of the benzene molecule are shown by B. Orelkin (Jour. Russ. Phys.-Chem. Soc., 1923, 54, pp. 493-532) to be situated at the corners of a regular octahedron. This conclusion is arrived at from geometrical considerations, which show that the above arrangement of the carbon atoms is the only one in which the thirty valency electrons of the benzene molecule can form a stable system. In support of this formula it is claimed that it explains why more or less than six carbon atoms cannot form an aromatic nucleus. The properties of the aromatic nucleus are explained as due to the peculiar arrangement of valency electrons around the carbon atoms, whereby each of the latter possesses two electrons in common with its neighbours. Sachs found that the relative distances of the *o*-, *m*-, and *p*- positions were as $1 : \sqrt{2} : \sqrt{3}$, and the same proportion is shown to hold for the formula now deduced. The space formulæ of naphthalene, anthracene, and chrysene are obtained by the condensation of two, three, and four benzene nuclei, and the angles of the space lattices of crystals of these substances are calculated from their molecular structure. These calculated values agree very closely with experimental values obtained by other workers.

LOW-TEMPERATURE CARBONISATION OF COAL.—The Fuel Research Board of the Department of Scientific and Industrial Research has just issued a Technical Paper No. 7 on "Preliminary Experiments in the Low-temperature Carbonisation of Coal in Vertical Retorts" (H.M. Stationery Office, 10*d.* post free). The paper may usefully be read in continuation of the report of the same body for the years 1920 and 1921, analysing the technical and economic problems to be faced in establishing a British industry of low-temperature carbonisation. The necessity for low operating costs, therein emphasised, implies a minimum of manual labour, and the use of the continuous vertical retort is one way of attaining this. An installation of such retorts on the Glover-West system now exists at the Fuel Research Station, Greenwich. Though designed for working under the high temperature conditions now current in towns' gas works, they have been employed in carbonisation trials, now reported, in which low working temperatures were maintained. The setting is ill adapted for securing the best results under such conditions, but the tests—admittedly of an exploratory character—have been carried out to obtain information likely to assist in the design of more suitable retorts. Such retorts have been constructed and trials are to be carried out in them. In the present tests flue temperatures ranged from 700° to 850° C., and it was found advantageous to inject steam into the retort, both to cool the coke and to assist in distributing heat through the charge. A coke was obtained containing about 7 per cent. of volatile matter and said to be suitable for use in domestic grates. The high proportion of breeze in the coke suggests trouble and loss in transportation. Per ton of coal, there was obtained a yield of 12-16 gallons of tar having a "low temperature" character and 18-28 lb. of ammonium sulphate. The yield of gas was only 45-50 therms per ton—very low from the gas-maker's point of view and fatal to commercial success unless the coke realised a very high price. As no finality is claimed for these results, the results from the new retorts will be awaited with interest.

HEAT LOSSES THROUGH HOUSE WALLS.—The Building Research Board of the Research Department has issued, as Special Report No. 7, accounts of the tests carried out at the National Physical Laboratory of the heat transmitted through walls of various types when one surface is hotter than the other, of those made in Norway on the heat insulating properties of the walls of experimental huts constructed in more than 20 different ways in use in that country, and of similar tests carried out in Sweden and in Germany. So far as the British tests have been conducted, they show that a solid gravel concrete wall and a wall of sand-lime bricks transmit about the same amount of heat under the same conditions, but that a wall of stock bricks only transmits about $\frac{3}{4}$ as much heat. A cavity wall of ordinary type transmits about $\frac{1}{2}$ to $\frac{2}{3}$ that of a solid wall according to the size of the cavity. The Norwegian results include the cost of construction and show in a remarkable way the low heat transmission through the less costly wooden walls of various types common in that country. Where cavity walls are used the best arrangement is to place the thicker portion in the interior. The Swedish results, so far as they go, confirm the above conclusions. The German results have led to a subdivision of the air cavity between thin concrete walls into six or more layers by means of paste-boards.

Scientific Exhibition at British Association Meeting.

THE ninety-first annual meeting of the British Association, which has just drawn to a close at Liverpool, was characterised by a new and important departure in the form of an exhibition of scientific apparatus, instruments, and diagrams. The exhibition was on the lines of that organised each year in London by the Physical and Optical Societies, which is so effective in bringing together the users and makers of physical apparatus, but its scope was naturally wider, and many branches of pure and applied science were represented.

In opening the exhibition on Monday, September 10, Sir Charles Sherrington commented upon the comprehensive and representative character of the exhibits, remarking that it was very appropriate that such a collection should be brought together, and that this—the first of its kind—constituted a definite development in the history of the British Association. He further referred to the remarkable advances in the making of scientific instruments during the last three hundred years, to the ever-growing importance of instrumentation, and to the unavoidable complexity of the apparatus needed for some of the simplest and therefore the most fundamental of scientific inquiries.

Admission to the exhibition was not confined to members of the British Association, to whom it was free, but the doors were opened to any member of the public on payment of the moderate sum of one shilling for one day only, while three times that amount guaranteed admission at any time during the fortnight of the exhibition. The results for the first week show that this arrangement was happily inspired, and that the exhibition was as popular with the outside public as with members of the Association. The number of daily tickets sold was quite naturally largely in excess of the number of season tickets, but the demand for the latter was quite sufficient to justify their issue.

The exhibition committee was fortunate indeed in having at its disposal the excellent accommodation afforded by the Central Technical Schools, Byrom Street, and the exhibits occupied the rooms on three floors of this magnificent building. The fine lecture hall enabled daily lectures, in some cases illustrated by cinematograph films or experiments, to be given by men of science, a feature which contributed in no small degree to the success of the exhibition. The popularity of these lectures is sufficiently illustrated by the fact that arrangements were made for two at least to be delivered a second time—"The Optophone," by Prof. Barr, and "Researches in Special Steels," by Mr. S. A. Main (Research Department of Sir Robert Hadfield's, Ltd.). Other lectures included "Ripples," by Prof. L. R. Wilberforce; "Research and Industry," by Sir Frank Heath; "Experiments on Coal Dust Explosions in Mines," by Prof. H. B. Dixon; "The Compass in Navigation," by Capt. Creagh-Osborne, R.N.; "Flame," by Prof. A. Smithells; "Kodachrome Cinematograph," by Dr. Mees (Kodak Co., London); "Developments in Wireless Telegraphy," by Commander Slee (Marconi Co., London).

Much attention was attracted by demonstrations, daily throughout the meeting, of the photophone exhibited by Prof. A. O. Rankine, and the optophone (Barr and Stroud, Ltd.). In the former, the transmitter or light modulator was installed in a room in St. George's Hall, and the beam of light, fluctuating in sympathy with the vibrations constituting the sounds to be transmitted, was thrown across the intervening space of some two hundred yards to the room in the Central Technical Schools where the receiving apparatus was located. The fluctuating light here controlled the electric current in a selenium cell, and the variable current actuated a telephone receiver. In this way demonstrations were given of the transmission of speech and music, and these made, in particular, a wide appeal to the lay mind, a result largely assisted by publicity given by the Press.

No less popular were the demonstrations of the optophone, the purpose of which is to enable the blind to read ordinary printed matter. In this, a selenium bridge is exposed to successions of sets of light pulsations, which vary with the forms of the letters passed over. Characteristic musical sounds are produced in a telephone receiver by each letter, constituting an alphabet readily learned.

The exhibition committee received the support of the National Physical Laboratory and of the Meteorological Office, Air Ministry. The exhibit of the former consisted very appropriately of specimen lenses for use in ships' lights, and master standards of colour for testing the colour screens of ships' lights. These were in accordance with the recommendations made in the Report of the Departmental Committee on Ships' Navigation Lights (1922), and formed an instructive display.

The exhibit provided by the Meteorological Department of the Air Ministry followed closely the lines of demonstrations given by that department at the two previous meetings of the Association, in Hull and Edinburgh. A wireless receiving set was employed to intercept the broadcast messages forming the daily international exchange of weather information, and, from these, weather charts were prepared, and forecasts made for the Liverpool area and the Irish Sea. Visitors were, in fact, able to see in miniature the complete working of a weather forecast service. These demonstrations were supplemented by a display of up-to-date meteorological instruments, and by diagrams and photographs of geophysical interest. Much interest was shown in the record of the recent earthquake in Japan, taken at the Bidston Observatory, and in a set of charts showing the progress of the depression which caused the destructive gales of August 29–30 of this year. One of these charts showed the depression completely defined over the Atlantic by one of the best sets of simultaneous observations from ships ever received in the Meteorological Office, and the accuracy of the forecasts issued on that occasion emphasises the practical importance of such reports.

One impression gained by a visit to the exhibition was that the field covered by the exhibits was not only a wide one, but also that very great care had been exercised in the choice of the material shown, having regard to the position of Liverpool as a great seaport and its location in an industrial area. It is not possible to deal in detail with the many interesting and instructive things which were to be seen, comprising, as they did, many striking exhibits in wireless transmission, in the manufacture of steel, in optical and electrical instruments, in instruments employed in navigation, including the gyro-compass, in the chemical and dye industries, in the manufacture of glass, in chemical apparatus, in recorders for use in the control of fuel combustion, in photography and photomicrography, in meteorological instruments, and in other branches of science and industry. Among the instruments which attracted special attention was K. C. Cox's selenium magnifier (H. W. Sullivan, Ltd.), which was shown working in connexion with a syphon recorder for long-distance submarine cable signalling, and is capable of giving magnification up to ten

thousand times the received signal, and higher in special cases. New wireless apparatus, shown by the Marconi International Marine Communication Co., Ltd., embraced direction finders for use in ships, a special installation for ships' lifeboats including direction-finding equipment, and a duplex telephone set—designed to enable ships within 50 miles of land to communicate by telephony with offices on land, utilising on land the ordinary telephone installation. The last is at present under trial at Southampton in co-operation with the General Post Office. Other very recent apparatus included a small X-ray spectrograph (Adam Hilger, Ltd.), made to the design of Dr. A. Müller, embodying details valuable for the analysis by crystal structure of crystals and powders, and a barograph of special construction for survey work (by Negretti and Zambra). The latter has a range of 4 inches on the chart to represent 1 inch variation of barometric pressure, and the instrument can be set to a standard barometer, anywhere from 25 in. to 31 in. of mercury, the temperature compensation being effective over this range. Mr. S. G. Brown's frenophone was another exhibit on which attention was focussed. This is a new "loud speaker" in which magnification of sound is obtained by an ingenious mechanical device dependent on the great friction existing between cork and glass.

But, in the space of a short article, justice cannot be done to all the interesting and instructive exhibits contained in the convenient and well-illustrated handbook issued by the exhibition committee. The local officers of the Association, the exhibition committee, and, in particular, the chairman of the committee, Capt. F. W. Bain, are to be congratulated on the success of this new departure, and it is to be hoped that they may be rewarded by seeing the present exhibition as the first of a long series in future years.

M. A. GIBLETT.

Terrestrial Magnetism in France.[1]

A DECREE of July 28, 1921, created an Institute of Geophysics attached to the Faculty of Science of the University of Paris, and the new institute has assigned to it the work in terrestrial magnetism previously entrusted to the Meteorological Service. There was established at the same time a Central Bureau of Terrestrial Magnetism for France and her colonies. The director of both bodies is the editor of the volume under notice, Prof. Ch. Maurain. He contributes an historical account of magnetic observations in France, and a study of disturbances due to electric traction. Recent magnetic history in France, as elsewhere, is mainly a tale of the devastating effects of electric traction. Parc St. Maur, which commenced its career as a magnetic observatory in 1883, had to be replaced in 1901 by Val Joyeux, and fears are now entertained for the future of Val Joyeux. There are already two electric lines in the district, one coming within 4400 metres, the other within 3000 metres of the observatory.

A discussion by M. Baldet of observations made at Berizaréa in Algeria represents magnetic work done in the colonies. The greater part of the volume, pp. 38-249, is, however, devoted to a discussion by M. Ch. Dufour of the magnetic observations at Val Joyeux from 1915 to 1921. This practically represents seven years' work rolled into one. In the earlier part of the memoir the results of the same species for the seven years appear in immediate succession. Thus we have $9\frac{1}{2}$ consecutive pages of Fourier coefficients for the diurnal variation of D (declination) and H (horizontal force) calculated for every month from January 1915 to December 1921, while pp. 60-94 are devoted to a description of the magnetic disturbances recorded during the 84 successive months. The principal magnetic storms are dealt with in 23 plates at the end of the volume, Z (vertical force) curves being reproduced as well as D and H. The time scale is only 1 cm. to the hour, and details of rapid oscillations are difficult to follow, especially for the largest storms, among which the storm of May 14-15, 1921, is pre-eminent. A rather unusual feature is that movement up the sheet represents decrease in all three elements. On p. 95 is a résumé of mean absolute values of seven elements at Val Joyeux from 1901 to 1921. The plan of the work then alters, the years being treated separately. The material given for each year has some special features. There are, first, for each month mean daily values for D, H, and Z, and hourly values confined to 6h, 12h, 18h, and 24h. The absolute daily maximum and minimum of D and their times of occurrence are included, and a word or two describes the character of the day. Then follow diurnal inequalities for the 12 months, apparently from all days, for 7 elements, and a table containing mean values for the 24 hours of the representative day of the year, derived respectively from all days and from quiet days. Following this is a most elaborate presentation of results from the five international quiet days of each month. Absolute values are given for each hour of each day for six elements.

The last part of the volume, pp. 250-298, contains a most valuable discussion of the magnetic results at Parc St. Maur and Val Joyeux from 1883 onwards by the veteran magnetician, M. A. Angot, late director of the Meteorological Bureau. This is a perfect mine of information for the magnetician. We have first diurnal inequalities for D, H, Z, and I (inclination) for the twelve months, derived independently from 18 years' records at Parc St. Maur, and from 17 years' records at Val Joyeux, stations both in the neighbourhood of Paris. Then we have diurnal inequalities for seven elements based on the whole 35 years, and ascribed to Paris. Following this there are Fourier coefficients for the 24-, 12-, 8-, and 6-hour waves corresponding to these inequalities. An elaborate investigation is made into the possibility of representing the annual change in the amplitude and phase of the several Fourier waves in terms of the longitude of the sun in its apparent annual path.

Another question minutely considered is the annual variation, meaning thereby the variation left in the mean monthly values of the elements after the elimination of the secular changes, assumed to progress at a uniform rate throughout the year. Use is made of mean monthly values of seven elements from 1883 to 1920, recorded in tables on pp. 278-284. The range obtained for the annual inequality in D, 0·23′, seems the smallest found anywhere as yet, but a suspicious feature in previous results has been the tendency for the apparent range to diminish as the number of years available has increased. For most of the other elements there are quite substantial ranges, *e.g.* 0·80′ in I (maximum in November, minimum in June), and 17·3γ in H (maximum in June, minimum in November). The ranges for these two elements are somewhat larger than those found for Kew[2] from a shorter period of years, but the

[2] Roy. Soc. Phil. Trans., vol. 216, p. 238.

maximum and minimum occur in the same months at the two stations.

A very complete investigation follows into the secular change, based on a table, on p. 287, of mean annual values at Parc St. Maur reduced to Val Joyeux, and at Val Joyeux, extending from 1883 to 1921. Some small differences may be noticed from M. Dufour's table on p. 95. On p. 288 reference is made to the possible influence of sunspots on secular change. As several magneticians have supposed such an influence to exist, it is important to note that M. Angot's results are wholly negative: "il semble impossible de retrouver . . . la moindre trace d'une périodicité de onze années." Secular change has followed almost identical courses at Paris and London. The change of D in late years has been very rapid, the easterly movement at Paris from 1916 to 1921 being 48·1′. H attained a maximum in Paris in 1912. After falling continuously until 1913, I has been rather oscillatory, there being a rise from 1914 to 1918, but a fall since.

As a final contribution to the subject of secular change, M. Angot has tried to represent the value of D at Paris from 1541 to 1921 by a simple harmonic fluctuation about a mean value. The formula giving the best results is

$$D = 6{\cdot}55° + 15{\cdot}85° \cos 2\pi(t - 1814)/480,$$

t being the date in years. The agreement between this formula and observation is quite good from 1541 to 1891; but since 1881 the excess of the observed westerly declination over that calculated has steadily increased until in 1921 it was 3·2°. The publication of this volume promises well for the future of the new Institute of Geophysics of the University of Paris.

C. CHREE.

University and Educational Intelligence.

THE Department of Aeronautics of the Imperial College of Science and Technology, which was established in 1920–21, has issued a pamphlet showing the courses available during the session 1923–24. The work is conducted in three sections, design and engineering, meteorology, and navigation, and a complete course normally occupies two years, the second often including research and experimental work.

THE university extension division of the University of Colorado exemplifies the wide range of services offered by a modern state university in America. This "division," described as "simply a vehicle by means of which the various departments of the university may be made available to the people of Colorado," includes not only a department of instruction (correspondence, class, vocational, and visual), but also a "department of public service" comprising bureaus of community organisation (for promoting public health, child welfare, recreation, and kindred subjects), business and governmental research, library extension, home-reading courses, high school debating league, high school visitation, and supply of public speakers. The range of public service which the university is willing to undertake is, in fact, limited only by its capacity to perform them.

FOR many years an admirable system of continuative education has been given in Great Britain in H.M. Dockyard Schools. Boys enter the dockyards as the result of competition, and the effect of this is a high standard of teaching in the primary and secondary schools of dockyard towns. When the apprentice has entered the dockyard, he has to attend school for eleven hours each week, partly in the afternoons in his working hours, and partly in the evenings. He is under strict naval discipline during these educational periods, and absence from school without sufficient cause leads to loss of pay, or to suspension or dismissal if the offence is repeated. Attendance is compulsory for every apprentice in the first year, but at the end of each of the four years of the normal course the least successful students are sent away from school. There is thus a continual weeding out of the mentally unfit, with the result that, at the end of the fourth year, the students who remain represent the best products of a wise combination of theoretical and practical training and are able to compete successfully for any scholarships in which applied science and mathematics are given prominence. The announcement of the result of this year's competition for Whitworth senior scholarships and Whitworth scholarships affords a remarkable example of this fact. The number of competitors for the former—of an annual value of 250*l*. tenable for two years—was 19, and for the latter—annual value of 125*l*. tenable for three years—was 142. Of the two senior scholarships awarded, one was to a former dockyard apprentice, now at the Royal Naval College, Greenwich. Of the six other scholarships, four were awarded to dockyard apprentices, and of the twenty-five Whitworth prizes of 10*l*. each given to unsuccessful candidates, twenty-one were awarded to dockyard apprentices. These splendid results are most creditable to the instructors in H.M. Dockyard Schools, and they show that the Admiralty system of education is a potent force for technical training and development in Great Britain.

THE prospectus for 1923–24 of university courses in the Manchester Municipal College of Technology contains the new regulations for the B.Sc. Tech., which provide for higher courses, distinct from, and at least one year in advance of, the ordinary degree courses, to extend over three years from the standard of the present intermediate examination for the degree, or the Higher School Certificate. The college offers courses of post-graduation and specialised study and research in various branches of engineering, applied chemistry and chemical technology, textile industries, applied physics, and mining engineering. The calendar of the Merchant Venturers' Technical College, Bristol, gives particulars of university degree courses, including the Bristol "sandwich" scheme of training for engineers. This comprises three periods of ten months each in the university, followed severally, the first by 14, the second by 2, and the third by 14 months in certain engineering works to which the university undertakes to recommend suitable students. Loughborough College, which has on its Board of Governors representatives of the Universities of Cambridge and Birmingham as well as of the Leicestershire County and Loughborough Town Councils, publishes full details of its equipment and courses in engineering and chemical technology and of its School of Industrial and Fine Art, Junior College, and extramural department, together with a list of some 250 students who qualified in 1922 for the College diploma, conferred for the first time in that year. The diploma course covers five years and its special feature is that, unlike the various "sandwich" systems, it provides for continuously concurrent training in engineering theory and practice. The Sir John Cass Technical Institute, London, announces, among others, special courses of higher technological instruction in brewing and allied industries, petroleum technology, colloids, alternating currents and electrical oscillations, metallography, foundry practice, mining and surveying.

Societies and Academies.

PARIS.

Academy of Sciences, August 27.—M. A. d'Arsonval in the chair.—Jean **Perrin**: Observations on fluorescence. The fluorescence of a solution depends on its concentration, thickness of layer, and light-absorbing power of the solvent. An attempt is made to define specific fluorescence, measurable by a coefficient independent of these factors.—D. **Mordouhay-Boltovsky**: Certain categories of transcendental numbers.—Jules **Baillaud**: The astronomical station of the Pic du Midi. This observatory is characterised by the purity of the sky and clear images. The advantage of the height (2870 metres) is not obtained at the price of undue fatigue on the part of the workers. Observations would appear to be possible except during the late winter and spring months.—A. A. **Guntz**: Phosphorescent sulphide of zinc. The partial substitution of cadmium sulphide in the zinc sulphide gives a more durable phosphorescence and causes changes in the colour of the light. It also renders the phosphorescent sulphides more easy to insolate.—André **Charriou**: The absorption of sodium hyposulphite by photographic papers. The elimination of sodium hyposulphite from photographic papers is much more rapid and complete, if the washing is carried out with solutions of sodium or ammonium bicarbonate instead of with water.—Ch. **Kilian** and V. **Likhité**: The development of *Hendersonia foliorum*.—Maurice **Piettre**: The chemical relations between humic materials and coal.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 9, No. 8, August 1923).—C. **Barus**; (1) The vibration of air in tubes capped at both ends. The air columns are actuated by telephones. Pressure changes are measured by an interferometer U-tube. With H-tubes and straight tubes there is a frictional but no special frequency effect. (2) The vibration of the air filament in quill tubes capped at both ends.—J. P. **Minton** and J. G. **Wilson**: Correlation between physical and medical findings on normal ears. Curves showing the relation between the root mean square pressures exerted on the ear drum by a telephone receiver diaphragm, plotted on a logarithmic scale, and the frequencies, plotted on a linear frequency scale, are used. In most of the fifty-four cases cited, the physical and medical findings for normality of the ear are in agreement.—T. Y. **Thomas**: The Einstein equations of the gravitational field for an arbitrary distribution of matter.—W. T. **Councilman**: The root system of *Epigæa repens* and its relation to the fungi of the humus. The roots of this member of the Ericaceæ, which is found only in America and Japan, are devoid of roothairs; the place of the latter appears to be taken by the hyphæ of a fungus which penetrate between and into the cells of the roots. The roots break up into a number of fine capillaries which ramify the humus near the surface of the soil. The relationship appears to be one of symbiosis.—J. V. **Leech**: The symmetry of the internal ears in flatfishes. Although the left eye of flatfish migrates during development until it comes to lie beside the right eye, the left ear remains in its original position. Examination of the left and right ears of numerous specimens of *Pseudopleuronectes americanus* and *Limanda ferruginea* showed no difference in structure. In consequence, the mode of action of the ears of these fish in equilibration is difficult to understand.—A. **Bramley**: Motion of an electric particle in a Riemann space. An infinitesimal particle revolving about the atomic nucleus describes a definite orbit with constant velocity.—W. M. **Davis**: (1) The marginal belts of the coral seas. The islands in the Pacific, in addition to the formerly glaciated islands of the colder seas, can be grouped in three categories: (*a*) Volcanic islands with cliffs, generally without submarine banks or coral reefs and mostly in the colder seas. (*b*) Islands with cliffs and submarine banks, sometimes with coral reefs; an intermediate or marginal belt about 5° wide between latitudes 25° and 30° north and south of the equator. (*c*) Volcanic islands without cliffs but having lagoons rimmed by coral reefs. The data supports the postulate of unstable islands associated with changes of ocean level and temperature, *i.e.* Darwin's theory modified by glacial control factors. (2) The depth of coral-reef lagoons. The stable rock platform hypothesis for the foundation of atolls is rejected on the grounds of the absence of cliffs and of such platforms on islands thought to represent uplifted atolls. Lagoon-enclosing reefs on subsiding foundations would produce lagoons of moderate depth; increased rate of subsidence would be counterbalanced by increased inwash of detritus. Shallow pre-glacial lagoons would be deepened by continued degradation during the lowering of the glacial ocean. The subsidence theory also accounts for submarine banks at varying depths in the coral seas.

SYDNEY.

Linnean Society of New South Wales, July 25.—Mr. A. F. Basset Hull, president, in the chair.—R. H. **Anderson**: A revision of the Australian species of the genus Bassia. Forty-two species of the genus Bassia are discussed, of which nine are described as new, and four as new combinations. A key to all the Australian species is given.—Jessie K. **Steel**: Anatomical features of the mature sporophyte of *Selaginella uliginosa*. The species is primitive. The radial type of shoots, together with the frequent occurrence of a Selago condition, the mixed arrangement of the sporangia in the cones, and the presence of four megaspores within the megasporangium, all point to a close relationship with the more primitive members of the Lycopodiales.—C. **Hedley**: Studies on Australian Mollusca. Pt. xiv. New species of the genera Hemidonax, Pitaria, and Umbraculum are described. From the Great Barrier Reef a considerable body of species is noted, which were named from New Caledonia and have now extended to Australia.

The British Dye-producing Industry.

IN a letter to the *Yorkshire Post* of September 12, Prof. W. M. Gardiner returns to the national problem of the British dye-producing industry, which is rapidly approaching the supreme crisis in its post-War history. Recognised at the outbreak of hostilities in 1914 as an essential factor in our national security and industrial welfare, the new dyestuffs corporation was then brought into existence in response to a general demand for the establishment of a home manufacture in dyes and intermediates.

Upwards of 7,000,000*l.* of government and private money have been expended in the land, building, plant, and general equipment of the British Dyestuffs Corporation Ltd. alone, and the other makers, of whom there are more than twenty, have also spent large sums in the extension of old works and the erection of new. On the technical side, the chemists employed in this new industry have made advances which are certainly revolutionary. Essential intermediates, hitherto not produced in Great Britain, are now manufactured in large quantities and of superior quality, and the range of British dyes includes eighty per cent. of the present requirements of our dye users.

On the economic side, however, the makers are in a position which is almost desperate. In spite of the fact that shareholders of dye-producing firms have received only meagre return on their capital outlay, the dye consumers are pressing continuously for reduction in prices because their foreign competitors have access to dyewares sold at prices with which no country with a stabilised currency can compete. At present, foreign dyes for which there are British equivalents are not admitted into Great Britain unless the British makers' price is greater than three times the pre-War price, and this measure of protection is being threatened. But even if the makers could get down to pre-War prices, it is doubtful whether the controversy on costs of production would cease, for in existing circumstances the German producer could profitably quote at far lower prices than those prevailing in 1914.

The chemists of the organic chemical industries, including dyewares, have shown themselves capable of the necessary concentration and patience required to build up the new scientific trades, but these essential national developments are doomed to failure in the near future unless the administrative leaders of the country in general, and of the dye-using industries in particular, can acquire what Dr. Duisberg, the head of one of the largest German colour works, speaking during the War, said England lacked, namely: "the faculty of fixing the eye on distant consequences and not merely on monetary results."

More Applications of Physics.

A Dictionary of Applied Physics. Edited by Sir Richard Glazebrook. In 5 vols. Vol. 5: Aeronautics—Metallurgy—General Index. Pp. vii + 592. (London: Macmillan and Co., Ltd., 1923.) 63*s*. net.

THE fifth and final volume of the "Dictionary of Applied Physics," now well known and justly famous, edited by Sir Richard Glazebrook, deals with two of the youngest physical sciences, aeronautics and metallography. The former occupies about two-fifths, and the latter the remainder of the book. The same plan is adopted as in previous volumes, *i.e.* there is a limited number of articles dealing with important aspects of the two sciences, written by men of high standing and authority in their subjects. Interspersed between these is a series of headings in alphabetical sequence, containing references to the articles in question. It is natural that many of the articles should have been contributed by present and former members of the staff of the National Physical Laboratory, Teddington. Whether, however, it was wise to make the proportion so high as it is in the metallurgical section of the volume may be questioned. A dictionary of this kind should represent as wide a range of authoritative opinion as it is possible to secure, and we think that the editor would have been well advised to draw, more than he has done, on the knowledge of metallographers occupying positions in the metallurgical industries.

The section on aeronautics opens with a valuable article on full-scale aerodynamic research by Mr. M'Kinnon Wood. The subject of experimental tests of the strength of aeroplane structures is dealt with lucidly by Mr. William Douglas, while various aspects of the theory of aeroplane structures are comprehensively treated by Mr. Cowley. Two articles by Mr. Guy Barr on aeroplane wings follow, one dealing with dopes, the other with fabrics. Mr. Barr also contributes a lengthy and interesting article on diffusion through membranes. The article on instruments used in air-craft, by Mr. Dobson, deals with many novelties. Prof. Bairstow contributes two articles, written with great authority, on the performance of air-craft and the stability of air-craft. A general outline of the theory of the air-screw is given by Mr. Arthur Fage, who also deals with the helicopter. This article may be studied in conjunction with that recently written by Prof. Bairstow in NATURE (August 18), entitled "The Helicopter: is it worth a prize?" The problem of the helicopter is that of an aerial machine "supported in the air by the thrust of one or more air-screws rotating about the vertical." As the author points out, many of these have been constructed, but only a few have supported their weight in the air, and none has been successful when judged from the point of view of practical utility. Experiments on air-ships constitute the subject-matter of an important article by the late Mr. J. R. Pannell and Mr. R. Jones.

The "engine" side of aviation is dealt with by the late G. H. Norman, Sqd.-Leader, R.A.F., in an article entitled "Air-cooled Engines for Air-craft." This contains valuable data on the comparative performances of air-cooled and water-cooled engines. At the present date the majority of engines are water-cooled, but the author evidently considers that there is likely to be a considerable increase in the use of air-cooled engines in the future. The saving in weight due to air-cooling may not be very great, and may in some cases be counter-balanced by increased head resistance. Its great advantage lies in the lower capital and attendance costs and the simplicity of the engine installation. Prof. J. C. McLennan contributes a short article on the production and use of helium. He estimates that from Empire sources, not more than about 12,000,000 cubic feet per annum can be obtained, the estimated cost being "not excessive." This, as he points out, would only keep a very few of the large air-ships in commission, even if diluted with 15 per cent. of hydrogen. The best method of extraction hitherto discovered consists in producing the refrigeration necessary to liquefy all the gases, except helium, by the cold obtained from the natural gas itself.

The subject of "Model Experiments in Aeronautics, their Theory and Methods," is dealt with comprehensively by Messrs. E. F. Relf and H. B. Irving, and the section closes with an article on "The Hydrodynamical Theory of Wing Surfaces," by Mr. H. Glauert.

Part II. of the volume is entitled "Metallurgy," but almost the whole of the subject-matter relates to what is usually called "Metallography." Dr. Haughton contributes excellent articles dealing with typical alloy systems, the construction of equilibrium diagrams, and the relationship between structure and physical constants. It is a pity that the constitutional diagram of the aluminium zinc alloys, on page 229, has been reproduced, since it is inaccurate in certain respects, and the correct diagram was published more than a year ago. This might well have been used and would have rendered unnecessary the footnote on page 230. Dr. Haughton has drawn his diagrams with the horizontal ordinates indicating weight percentages. It is not clear why he has preferred this arrangement. The system of plotting atomic percentages on the horizontal ordinates has many advantages. The diagram of the iron nickel system reproduced on page 235 is incomplete in the upper range of temperature where the δ to γ inversion of iron takes place. The only metal the

metallurgy of which is described in this volume is aluminium, presumably on account of its use in air-craft, but it is not the only metal used, and it may be questioned whether it was worth while introducing it. The metallurgy of aluminium is adequately described in a number of text-books. Similarly, it is not clear why the electrolytic refining of copper has been singled out for treatment. A general article on the principles of electrolytic refining giving illustrations from various metals, would have been more useful.

Mr. Francis FitzGerald has compressed a remarkable amount of information into his article on electric furnaces. It gives exactly the kind of treatment of the subject that is required in a volume of this kind. Mr. Coad-Pryor has written two articles, both of them very good. That on "Furnaces for Laboratory Use" is of moderate length, while the one on "Refractories" is of considerable dimensions. They are packed full of information and the treatment is admirable. Of very solid merit also are the two articles by Dr. Hanson, one on iron carbon alloys, the other on the defects and failures of metals. The former, however, is rather perfunctory in its reference to cast-iron. It deals with pure iron carbon alloys, and has only a very slight reference to commercial cast-irons containing silicon, manganese, phosphorus, and sulphur. The article on the defects and failures of metals is most valuable. It represents what may be called National Physical Laboratory experience at its best. The author, however, is incorrect in attributing the growth of cast-iron on repeated heatings to the pressure caused by the formation of oxides of iron. The main cause, at any rate, is the volume increase caused by the separation of silica. The statement on page 372 that "a 'crystalline' fracture (one containing bright facets along which rupture of the crystals has occurred—not an inter-crystalline fracture) indicates by the size of the facets, the general size of the crystal structure of the material," is scarcely correct in this unqualified form, seeing how greatly the fracture may be made to vary according to the method of producing it.

Dr. Rosenhain contributes seven articles, and these constitute between one-third and one-quarter of the entire metallographical section. He deals with (1) some special alloys, (2) aluminium alloys, (3) the microscopic examination of metals, (4) the relations of strain and structure in metals, (5) the thermal and mechanical treatment of metals, (6) the thermal study of metals, and (7) the microstructure of metals and alloys. The most considerable of these is the article on the relations of strain and structure and the conception of amorphous metal. The subject is handled with the author's well-known ability. It is well to remember, however, that the conception of amorphous metal is not by any means generally accepted to-day among metallographers, and it may be doubted whether anything is gained by such a sentence as appears on page 397—"At the present moment indeed, even those who, on certain grounds, vehemently oppose this theory have no alternative to offer which can afford any satisfactory explanation of the great group of facts which this theory so readily co-ordinates." In the section headed "Tempering and Quenching" (page 411), Dr. Rosenhain attributes the hardening of a carbon steel by quenching to "the development of a very large number of minute crystallites of both α iron and cementite," and the existence of an "envelope of amorphous iron which is so highly viscous as to be, in effect, an intensely hard solid." As to this, there is no evidence of the formation of cementite in a properly quenched steel. More causes operate in the hardening of steel by quenching in water than are indicated in this article.

Sir George Beilby's striking work on metal aggregates receives attention in two articles written by Mr. W. D. Haigh on the aggregation of solids and the flow of solids. There is a long and very useful article by Dr. W. H. Hatfield on "Special Steels," which, with the valuable article by Sir Robert Hadfield on "Manganese Steels," does something to bring the "works" atmosphere of applied science into this section of the dictionary. The volume closes with a detailed index of the subjects dealt with in aeronautics and metallurgy, and finally with a general index of the principal articles in the five volumes.

Tubicolous Worms.

(1) *A Monograph of the British Marine Annelids.* Vol. 4, Part 1: Polychæta—Hermellidæ to Sabellidæ. Pp. vii+250+plates 112–127. 50*s*. net. (2) Vol. 4, Part 2: Polychæta—Sabellidæ to Serpulidæ; with Additions to the British Marine Polychæta during the Publication of the Monograph. Pp. xii+251–539+plates 115–117 and 128–138. (Published for the Ray Society). By Prof. W. C. McIntosh. (London: Dulau and Co., Ltd., 1922–23.) 50*s*. net.

THE volumes under notice constitute the last two parts of "A Monograph of the British Marine Annelids." The Council of the Ray Society in the preface to the final volume, issued with the last part, "believe that they are interpreting the feelings of the members of the Society in offering to their President congratulations on the completion of this monograph, of which the first part was published no less than half a century ago." This is an expression in which all zoologists would wish to join, and rejoice that Prof.

McIntosh sees in his eighty-fifth year the completion of his magnificent work. Through the years he has pursued with such admirable singleness of mind, amid many other occupations, the study of this neglected group of marine animals. When he so modestly "hopes that they are left in a better state than he found them, thanks to the greater attention zoologists in every clime have bestowed on the Marine Polychaets," we can only reply that his name stands foremost among investigators of the Polychæta during a period of great and unexampled progress, in which his broad comprehensive studies have been supplemented, and are now necessarily succeeded, by the work of specialists in the different families.

The Ray Society is scarcely less to be congratulated on the way in which it has persevered with the production of the final parts of the monograph during the lean years after the War. So much stands to the credit of the Ray Society in the past for its wonderfully illustrated volumes by Allman, Alder and Hancock, and many others, which have done so much to create the reputation of British marine zoology, that we cannot sufficiently praise the vigour and enterprise, with unimpaired excellence of execution, which the Society still displays. It is earnestly to be hoped that it may receive the increased support from zoologists which it now so greatly needs.

(1) "Such synonymes as would signify *mason* or *potter*, might be aptly applied in explaining the character and habits of the Terebella. Nothing could be more appropriate, for this animal is alike distinguished by address and perseverance in producing works of art." This tribute to one of the despised tribe of worms is paid by Sir John Dalyell in "The Powers of the Creator declared in the Creation," a book which embodies his patient and extended observations on the habits of marine animals. In the first part of the last volume of Prof. McIntosh's great monograph five families of tube-building polychæts are described, the Hermellidæ, Amphictenidæ, Terebellidæ, Ampharetidæ and Sabellidæ, and the first three exhibit in the highest degree that craftsmanship which always awakens a sympathetic chord in the human observer.

The Terebellidæ, of which twenty-four species are here described, is the best known of these families. The basis of the tube which they inhabit is a secretion of the skin glands which often hardens to the consistency of parchment. In this while it is still soft the animal embeds, on the outer surface, the foreign bodies which it so assiduously collects. It is a common but always fascinating sight to see the countless tentacles of a terebellid spreading in all directions from the opening of its tube. With a lens, a multitude of particles can be detected moving along the ciliated groove on the surface of each tentacle, toward the mouth. Prof. McIntosh quotes the following passage from Dalyell describing this never-ceasing activity: "Nothing is more surprising than the attention of so humble an artist being directed towards such a variety of operations at the same time. Many tentacula are searching after the materials—many in collection—many bearing them to the edifice—some quitting their hold—others recovering the load—while the architect itself seems occupied in kneading masses in its mouth, disgorging them successively, or in polishing the rude workmanship resulting from its labours." The worm thus described, the "Potter" of Dalyell, *Amphitrite figulus*, builds tubes of mud, but others like *Lanice conchilega* use grains of sand or even carefully select fragments of shell. There are still more fastidious forms like those Japanese examples mentioned by Prof. McIntosh as collected by the *Challenger*, which gather pine needles and stick them lengthwise on the tube, and in the Cretaceous there occur tubular structures composed of bones and scales of fishes which Bather assigns to the activities of Terebellids.

The Amphictenidæ include such well-known forms as *Pectinaria belgica*, a very abundant worm. The reviewer remembers seeing the Belgian coast in 1917 strewn with millions of this form washed out of the sand after heavy weather. Their slightly curved tubes are miracles of workmanship. Prof. McIntosh in his description of this and other forms has quoted largely from the work and reproduced some of the drawings of Mr. A. T. Watson, to whom we owe so many fascinating accounts of the methods of annelid artificers.

If the tubes of the Terebellids and Pectinaria are usually hidden from view, Sabellaria among the Hermellidæ often forms conspicuous masses of firmly cemented tubes between tidemarks covering large surfaces of rock. Unlike other "social" polychæts (e.g. Filograna, Phyllochætopterus and *Potamilla torelli*, all described in this work) they do not reproduce asexually, and some other explanation must be sought for their gregarious nature.

The Sabellidæ again are among the most interesting of tube builders. The crown of finely divided processes around the head, so beautifully portrayed in Prof. McIntosh's plates, are referred to here (as is usual elsewhere) as branchial, but we venture to think that Bounhiol's experiments, made in 1890, show that they have no special respiratory value. But, indeed, the comparative study of the respiration of the tubicolous worms offers a very profitable investment for the time of a biologist.

(2) In the second part of Vol. 4 the description of the Sabellidæ is continued, and the last family, the Serpulidæ, is treated. Here the tubes are always

calcareous, and one of the cephalic filaments is usually modified to form an operculum. One of the most interesting features of the family is the remarkable pigmentation of the cephalic filaments, often very variable in the same species, giving the animal a charming flower-like appearance, a phenomenon which has still to be investigated thoroughly. Among British species the condition is best developed in *Pomatocerus triqueter*, which, nearly everywhere, whitens the stones and rocks between tidemarks. Other characteristic British forms, amply treated here, are *Serpula vermicularis*, so often attached to the shells of Pecten in the coralline zone, and Filograna, the coral-like masses of which are frequently taken in the dredge.

Lastly there is an addendum of no less than seventy-eight species which have been discovered or described as British, too late to appear in their proper places. Of the many co-workers whom the author cites as responsible for these additions to the British fauna, there must be specially mentioned Mr. Southern, of the Irish Fisheries Department, who, working in the years just before the War, at Clare Island and elsewhere, obtained a plentiful harvest of unsuspected forms, including eighteen entirely new species. "Truly the riches of the marine fauna of the west coast of Ireland are by no means exhausted," Prof. McIntosh is constrained to exclaim, and we must hope that Mr. Southern may be able to complete his faunistic work.

The wonderful charm of the drawings by the late Mrs. Gunther and Miss Walker, and the success of their reproduction, have so often been commented upon by reviewers of earlier parts that we can do no more than re-echo their praise. One feature of the volume is, however, almost unique: that is the bibliographical collation of the parts as issued, compiled with the index by Mr. G. A. Smith.

Universities and National Life.

The Older Universities of England: Oxford and Cambridge. By Albert Mansbridge. Pp. xxiv+296+8 plates. (London: Longmans, Green and Co., 1923.) 7*s*. 6*d*. net.

MR. MANSBRIDGE scores with both barrels. He appeals to both of the classes into which (relative to his book) the world is divided—those who have been at a university and those who have not. In any case, although he has the detachment which comes from never having been through the university mill himself, he not only loves and appreciates the university and what it stands for, but also has actually added something to its nature and functions. By his initiation of the Workers' Educational Association, he gave a new and fuller content to the whole extra-mural side of university activity, and helped to spread the universities' influence more rapidly and more extensively than could have been done in any other way. Add to all this that he was a member of the recent Royal Commission on Oxford and Cambridge, and it will be seen that he has advantages that the most learned historian cannot despise.

For it is as a historian that Mr. Mansbridge, wisely enough, chooses to treat his subject. In his pages we see the genesis of English universities in the ferment of the twelfth century, the beginnings of the college system, its expansion by such men as William of Wykeham, Henry VI., and Wolsey, the involvement of the universities in politics, the submergence of their original purpose beneath the flood of wealth and birth in the eighteenth century, the gradual reappearance of that purpose from the middle of the nineteenth century onwards, the adjustment of the curriculum to modern needs, the growth of a new university organ in extra-mural education. . . .

We are not allowed to forget the continuity and vitality of the current of scholarship and learning, nor to lose sight, under a mass of academic detail, of the university's position in the body politic. Nor is that all; Mr. Mansbridge, for all his idealism (which may prove almost embarrassing to a certain type of overworked and matter-of-fact "don"), can appreciate and even be affectionate to the failings of Oxford and Cambridge. The noblemen and gentlemen-commoners, even at their most foppish, amuse him; he sees through to the human heart below donnishness, and smiles indulgently on port.

For this alone the book is worth reading—because it is a short and well-written and appreciative history of our two oldest and greatest seats of learning. But it is worth reading for more important reasons. It is worth reading by the university-trained man, partly because Mr. Mansbridge's wistful regret at his own lack of that training helps to fuller realisation of its meaning and values, and partly because his concern for the extension system and the W.E.A.'s fine work puts the university in a new setting for him, relates it to new aspects of national life. It is worth reading also by all those who have not received a university education and yet are concerned in any way with domestic politics, because it will help reveal to them what a university can and should be—what an ideal to the individual, what a force in the community.

Mr. Mansbridge is a rebuke to the diehard (generally Tory, practical, and well-to-do), who exclaims that education is a curse and a burden and higher education in particular an unpractical folly; and a rebuke no less to those violent spirits of the Left who see in all universities, and especially in Oxford and Cambridge, some

dodge of capital, and hate the aristocracy even of learning. To him the university is simply the corporate and social expression of civilisation's mind; and, as with the mind of an individual, although its fullest cultivation is in one sense a luxury, yet in another and broader view, it is the highest necessity.

Avian Minstrelsy.

Songs of the Birds. By Prof. Walter Garstang. Second edition. Pp. 115. (London: John Lane, The Bodley Head, Ltd., 1923.) 6*s*. net.

We have before us the second edition of this agreeable and very suggestive little book, the original issue of which was noticed in Nature of August 12, 1922. A new song has been added and two passages have been revised, but otherwise the alterations are merely verbal. Mr. Shepherd's quaint little sketches of the songsters again add to the pleasure of the reader.

The book, we may recall, begins with an important essay in which Prof. Garstang discusses the nature of avian song, the rôle it plays in the life of the birds, and the very interesting evolutionary aspects of the subject. From that he proceeds to the vexed question of the symbolic representation of song, and after having propounded his thesis on this point he begins his series of representations of the music of the different species. The reasons which he gives for the adoption of his particular form of representation cannot fail to carry some measure of theoretical conviction to the reader, based as they obviously are on a thorough appreciation of bird song aided by a knowledge of music and a sense of poetry. It is harder to apply the practical test as to whether the representations do indeed convey more adequately than former attempts an idea of the various songs, for one has to bear in mind the existence of individual differences both in the hearing of the songs and in the interpreting of the written symbol: one hesitates, indeed, to express a definite opinion until students of the subject have had further experience in using the new method. If, however, either these "first fruits" of Prof. Garstang's studies or some future elaboration of them can in time be regarded as making possible the adequate representation of different songs on paper, he will have succeeded in making good a deficiency of which the present existence is evident in every text-book of ornithology.

In the preface to the new edition the author replies vigorously to such of the reviewers of his first edition as were hostile in their criticisms, and in so doing he also takes to task our own by no means unappreciative notice for not having discussed his auxiliary verses from a scientific point of view. Lest we may seem unjust in this respect we may here quote Prof. Garstang's own account of his method and of the part which his verses play therein: "The peculiar quality or *timbre* of each bird's voice and the resonance of each sound have been imitated as closely as possible by a selection of human consonants; the composition of the song has been represented by the appropriate repetition, modification, or contrast of selected syllables; the syllabic rendering has been cast in a corresponding rhythm; and round this chosen sequence of syllables a song has been woven to capture something, if possible, of the joy or of the attendant circumstances which form the natural setting of his song." We have certainly no wish to quarrel too seriously with our author as to where scientific method properly ends and where more emotional vehicles of thought properly begin. In his new preface he quite truly says that "The exploration and illustration of the borderlands of Science and Art will not end with my adventure": we may add the hope that even his own adventure into these fields is by no means concluded.

Prevention of Vibration and Noise.

The Prevention of Vibration and Noise. By A. B. Eason. (Oxford Technical Publications.) Pp. xii + 163. (London: H. Frowde and Hodder and Stoughton, 1923.) 15*s*. net.

This volume, as the author states in his preface, does not profess to contain anything not already known, but is a more or less classified account of the work of various experimenters on the subject of which it treats. Beginning with a useful but not complete bibliography, and a note on the problems to be investigated, later chapters treat of "annoying" vibrations and their amplitude; the means and apparatus which have been used to measure them, the vibrations of buildings, bridges, and other structures; means of damping vibration, the transmission and isolation of noise; and ending with an account of balancing machines, *i.e.* machines for determining whether, and how much, any revolving part is out of statical or dynamical balance.

As showing what has been done in these matters. the book is useful for reference, but its value would have been much increased by a more critical examination of the elements of the whole subject. It is difficult in many places to know whether the author is giving his own views or restating those of the experimenters whose results he summarises.

In defining "annoying" vibration, scarcely sufficient attention is given to the differences in surrounding conditions. What would be "annoying" in Mayfair might be unobjectionable in Poplar. Where wood or asphalt pavement prevailed, the introduction of granite

sets would certainly cause complaint. In describing the different forms of apparatus which have been used for measuring vibrations, no hint is given as to the trustworthiness of the results. This is an important omission, for in the greater number of those instruments the records are an imperfect catalogue of peculiarities of the instrument rather than of the magnitude of the external vibrations which they were designed to measure. All such instruments have natural periods of their own, and one of the most important points in their design should be to arrange that neither the slowest nor any of the more rapid natural periods shall approach those of the imposed vibrations, and since in most cases the imposed vibrations are (like white light) made up of a great many arbitrary disturbances, this is not a condition which it is easy to fulfil. Many mistaken diagnoses have been made from neglecting the effects of resonance on the recording apparatus, and from supposing that a large recorded amplitude necessarily indicates a large external vibration.

Perhaps the most interesting chapter is that on the isolation and damping of sound, in which many examples are given of successes and failures in practical attempts in this direction. In most of these the actual results might have been anticipated. In speaking of the minimum audible sound (as in reference to the least sensible vibration) insufficient prominence is given to the effect of the surrounding conditions. In an absolute silence many experiments have shown that a sound, the wave amplitude of which is a twenty-five millionth of an inch, can be heard, but in the midst of other noises, if the amplitude of the loudest of these is taken as unity, another sound with an amplitude of 1/15 is only just audible, so that the greatest and least intensities which can be appreciated simultaneously are something like two hundred to one.

With regard to the isolation of sound, an absolute barrier to the propagation of vibrations may be set up either by complete reflection or complete absorption, but when the amplitude is large and the absorption rapid, a gradual change may probably occur in the absorbent. The secular change in the efficiency of sound-absorbing materials is not mentioned.

In reference to the acoustic qualities of halls and rooms, most of the experimenters whose work is quoted seem to consider that "good" and "bad" depend on the rate at which vowel sounds and musical notes are damped, but it is not uncommon to find rooms which are good for music but bad for speech, and it is the effect of the resonance of the room on the consonants rather than on the vowels which determines whether spoken words are clearly heard.

Though there are many published papers on the subjects which come under the head of "vibration," Mr. Eason's is the only book in which any collection of their results has been attempted, and notwithstanding some defects (chiefly of omission), it should form a very useful addition to the literature of the subject. A. M.

Our Bookshelf.

Advanced Practical Physics for Students. By B. L. Worsnop and Dr. H. T. Flint. Pp. vii+640. (London: Methuen and Co., Ltd., 1923.) 21*s*. net.

TEACHERS of experimental physics will find much that is useful and suggestive in this volume. Though some experiments of an elementary character have been included, the work is intended for advanced students who are working for a pass or honours degree. The bulk and the price of the book might have been reduced materially by the omission of much that is common to many elementary text-books. In some cases full experimental details are given, while in others the description is insufficient to enable an ordinary student to carry out the necessary manipulations. Little attention is given to the degree of accuracy to be expected.

Many recent experiments and modern forms of apparatus have been described. We may mention in particular the determination of the ratio of the charge to the mass for an electron by means of the Zeeman effect using a Lummer-Gehrcke plate, and also by Sir J. J. Thomson's method. From the account given in the book the student might infer that the latter method is due to Braun. There is a useful chapter on the quadrant electrometer (in which Wheatham should be Whetham), and a section on the three-electrode valve.

The most striking feature of the work is the stress laid on the theoretical side of the subject, the aim being to make the course practically independent of other treatises, at least as regards immediate reference. To aid this scheme an introductory chapter on the calculus has been included.

It is to be regretted that the proof-sheets were not submitted to a literary critic, as there are too many examples of careless or ungrammatical construction, and the punctuation needs amendment in many places. The wholly inadequate table headed "Units" needs revision: the value for the electrochemical equivalent of hydrogen has long been superseded, and to give the charge on an electron as $4 \cdot 71 \times 10^{-20}$ E.S.U. is unpardonable.

Mechanical Testing: a Treatise in Two Volumes. By R. G. Batson and J. H. Hyde. Vol. 2: Testing of Prime Movers, Machines, Structures and Engineering Apparatus. (The Directly-Useful Technical Series.) Pp. xi+446. (London: Chapman and Hall, Ltd., 1922.) 25*s*. net.

THE first volume of this work dealt with the testing of materials of construction; the present volume concludes the treatise and contains a great deal of matter which will be of service to all who are interested in the testing of machines and structures. The selection of a suitable dynamometer is of vital importance in the testing of an engine or machine, and, roughly, one-quarter of the volume is devoted to different types of this instrument. This section includes traction dynamometers such as

are used in railway work, and the Lanchester machines for the testing of worm gears. Other sections deal with lubricants, friction tests on bearings, vibration tests, and static and dynamic balance.

The part of the volume devoted to tests on structural elements contains methods of testing concrete slabs and beams, plain and reinforced, and also columns of various types. Much of the work which has been done on this subject has been carried out in America, and we note that the authors have dealt justly with it in the space at their disposal. Tests on cutting tools, aircraft models, and other miscellaneous tests conclude the volume. As was the case in the first volume, a good deal of the apparatus described is installed at the National Physical Laboratory, but the authors have not forgotten that research cannot be confined to one place, nor to one investigator or group of investigators. The complete treatise will be welcomed by all who are engaged in the testing of engineering materials and appliances.

(1) *Oil Power.* By S. H. North. (Pitman's Common Commodities and Industries.) Pp. ix+122. 3*s.* net.
(2) *Internal-Combustion Engines.* By J. Okill. (Pitman's Common Commodities and Industries.) Pp. xi+126. 3*s.* net.
(3) *The Diesel Engine.* By A. Orton. (Pitman's Technical Primers.) Pp. x+111. 2*s.* 6*d.* net.
(London: Sir Isaac Pitman and Sons, Ltd., 1923.)

THE general reader who desires information regarding oil fuel and the practical methods of using it will find much of interest in these three little books. The greater part of (1) is occupied with descriptions of oil burners as used in furnaces. This system is employed to a large extent in marine and locomotive boilers. The question of oil storage at various ports is of vital importance for the supply of oil-fired vessels, and is dealt with towards the end of the volume. The first thirty-two pages in (2) are devoted to the gas engine, and the greater part of the remainder deals with oil engines of different types. The book is up-to-date in the matter of the engines selected for description, and there are sections on aero-engines, tractor engines and turbines. The Diesel engine is of sufficient commercial importance now to warrant a separate volume, and this is provided in (3). Here we find descriptions of the arrangements and methods of working of both four-stroke and two-stroke Diesel engines, and a short discussion of the power developed and the efficiency. The student of heat engines will of course require a great deal more than is contained in these books. They are, however, very suitable for those readers who wish to be informed as to what has been accomplished in this important branch of engineering.

British Museum (Natural History). British Antarctic (Terra Nova) Expedition, 1910. Natural History Report. *Botany*, Part 3: Lichens. By O. V. Darbishire. Pp. 29-76 + 2 plates. (London: British Museum (Natural History), 1923). 7*s.*

DR. DARBISHIRE's account of the lichens is the third of the reports to be issued on the botany of Captain Scott's Antarctic expedition of 1910. Reports on the seaweeds (by Mr. and Mrs. Gepp and Mme. Lemoine) and on the freshwater Algæ (by Dr. Fritch) were published in 1917.

Seventeen species were collected, eight of which proved to be new, and are described and figured in the present publication. With the exception of one Lecidea, the new species belong to the genus Buellia. The lichens were all found on rocks, mainly granite and gneiss, at Cape Adare and Evans Cove in South Victoria Land. When describing the lichens brought back by the Swedish Antarctic Expedition (1901-3) in 1912, Dr. Darbishire gave a summary of the species known at that time from the Antarctic area; their number was 107; this has now been increased to 208, mainly by the material brought back by the second French Antarctic Expedition of 1908-10, which was reported on by the late Abbé Hue. The value of the present brochure is enhanced by the inclusion of a complete list of the species recorded from the Antarctic area, that is, from localities to the south of the 60° S. parallel, to which are added keys to the genera and species. Twenty-three per cent. of the species are also found in the Arctic regions, and the author notes a striking similarity of the Arctic and Antarctic lichen flora in regard to the proportion among the known species of the chief lichen forms.

The Preparation of Plantation Rubber. By S. Morgan. With a Preface and a Chapter on Vulcanisation by Dr. H. P. Stevens. Pp. xvi+331. (London, Bombay and Sydney: Constable and Co., Ltd., 1922.) 21*s.* net.

BOTH editions of Mr. Morgan's useful book on plantation rubber are now out of print, and in preparing a third edition the opportunity has been taken to revise completely the original work, and to incorporate in the new volume the results of the experimental research in practically all branches of the business of preparing rubber for the market which has been carried out by Mr. Morgan in the course of his work as Scientific Officer to the Rubber Growers' Association in Malaya. In doing so, the book has been virtually re-written, and it now forms a complete and authoritative guide to the modern practice of a rubber plantation, from the planting of the tree to the packing of the rubber for export. The subject has been usefully rounded off by the addition of a series of three chapters on the vulcanisation of rubber, including an account of the methods of testing the material for industrial use. This section of the book has been specially written by Dr. Stevens, consulting chemist to the Rubber Growers' Association in London, and is based on the researches on vulcanisation carried out by him for the Association over a period of about ten years. Altogether the volume is an admirable handbook, and with periodical revision should remain the standard work on the subject.

Die Stereoskopie im Dienste der Photometrie und Pyrometrie. Von Carl Pulfrich. Pp. iv+94. (Berlin: Julius Springer, 1923.) 3*s.* 4*d.*

THE physiological optical effect on which the photometrical method made use of in the instruments described in Prof. Pulfrich's book is based was described in NATURE of May 12, p. 648, and May 19, p. 691. In one of Prof. Pulfrich's instruments a pair

of fixed and moving marks is employed, which is observed by both eyes simultaneously through a pair of telescopes provided with a suitable system of prisms; in others two pairs of marks are made use of, one of which is seen in the middle of the field of view of each of the two telescopes, so that the appearance is that of a single pair. The two moving marks are geared together, and driven either by hand or by a small hot-air motor. If the fields of view of the two telescopes are equally "bright," the mark appears to move to and fro, horizontally, in a straight line, its point passing just above the point of the fixed mark; a difference of brightness makes it appear to revolve round the fixed mark. This is independent of the colour of the two lights which are being compared. It is also possible to adjust the two sides of the apparatus to equality of brightness with an accuracy of 2 to 3 per cent., however great the difference of colour may be, provided the observer has sufficient experience, and good spectroscopic vision. In the stereospectral photometer, two monochromators are employed, one for each telescope, so that practically monochromatic light of different wave-lengths can be employed. A form of photometer, which enables one-half of the spectrum to be balanced against the other half, promises to be valuable in pyrometry.

Malaya: the Straits Settlements and the Federated and Unfederated Malay States. Edited by Dr. R. O. Winstedt. Pp. xi+283. (London, Bombay and Sydney: Constable and Co., Ltd., 1923.) 12*s.* net.

This authoritative and comprehensive handbook will come as a boon to all who are interested in or in any way connected with the Malay Peninsula. The editor, a well-known authority and the author of several works on the Malayan language, is himself responsible for the chapters on the population, the ethnology, and languages of the Peninsula; Malayan literature; arts and crafts; religion and beliefs; and history and archæology, as well as the account of the Eurasian, Chinese, and other races of the country.

Other chapters are the work of experts in their respective departments. Mr. J. B. Scrivenor, the Government Geologist, describes the geography, geology, and mineralogy of the country, as well as its mining industry. Dr. F. W. Foxworthy deals with the flora and forests, and Mr. F. C. Robinson of the Federated States Museum with the fauna. Mr. B. J. Eaton, Director of Agriculture, deals with this and other industries, while Mr. Pountney, Financial Adviser to the Straits Settlements, analyses revenue and expenditure. The sections on the Straits Settlements, the Federated and Unfederated States, which will be found particularly helpful, are the work of the editor. An adequate, if not lengthy, bibliography is an excellent guide to those who seek further information. The book is well illustrated and well produced.

A Tested Method of Laboratory Organisation. By S. Pile and R. G. Johnston. Pp. xx+98. (London: H. F. and G. Witherby, 1923.) 7*s.* 6*d.* net.

The authors of this little book were associated with a co-operative laboratory established during the War by a number of Birmingham brass firms, and their conclusions are mainly based on experience gained in that laboratory. They give many useful notes on the equipment and arrangement of works and control laboratories, on the preparation of samples, and on the methods of recording the source of the sample and the results of its examination, whether analytical, mechanical, or physical. Their treatment of the subject of laboratory books and the entering of results is very thorough, and they go so far as to describe a system of costing in units by means of which a monetary value may be attached to each operation. While the scale of the work is too small for it to serve as a manual of laboratory equipment, it will be found particularly useful by those who have to instal a small laboratory in a works, especially in one of the metallurgical industries. The question of the relations between the superintendent and his staff is also dealt with, but the closing chapters, under such headings as "The Mentality of the Scientist," seem rather out of place in an essentially practical note-book.

Among Unknown Eskimo. By J. W. Bilby. Pp. 280+16 plates. (London: Seeley, Service and Co., Ltd., 1923.) 21*s.* net.

The Eskimo of Mr. Bilby's title can be accurately described as "unknown" only in relation to the public for whom he writes—a public which normally does not have access to scientific publications. His account of the customs, modes of life, and beliefs of the Central Eskimo of Baffin Land is, however, something more than a book with a merely popular appeal. A residence of twelve years among these tribes qualifies him to give ritual and belief their proper setting and perspective in the everyday round in a manner which is not always possible in an analytic study. This has a value which anthropologists will readily acknowledge; but Mr. Bilby's intense appreciation of the native attitude of mind to tribal observances, and his keen insight into the dynamic relation of such observances to conduct, have obscured the fact that these do not necessarily tell the whole story. Accordingly, he is prone to offer as an interpretation of native practices the immediate social effect and the psychological factors which come into play in certain elements of ritual, to the neglect of deeper causes. An appendix gives a valuable list of some fifty departmental deities of the Eskimo with their attributes.

Edmund Loder; Naturalist, Horticulturist, Traveller and Sportsman: a Memoir. By Sir Alfred E. Pease. With Contributions by St. George Littledale, Charles G. A. Nix, Lord Cottesloe, J. G. Millais, and W. P. Pycraft. Pp. x+356. (London: John Murray, 1923.) 18*s.* net.

The friends and acquaintances—and of a man so accomplished and of such wide interests as was Sir Edmund Loder, these are many—will be glad to possess this "miniature" of his remarkable personality. Sir Alfred Pease has not attempted to depict a life-size portrait; but by wise selection, and with the assistance of other contributors, he succeeds in conveying a very clear impression. The reviewer can perhaps pay no higher tribute than by stating that though he was not privileged to know Sir Edmund personally he closed the book with the feeling that he knows well what manner of man he was.

Letters to the Editor.

The Control of Malaria in the Malay Peninsula.

BEFORE Sir Ronald Ross's epoch-making discovery, there was no more puzzling problem in medicine than the cause of malaria; no secret in Nature more cunningly hid than the malaria secret. Malaria was known to be connected with swamps, and to be reduced by drainage and cultivation. Yet, as if merely to confuse, men found that to flood some swamps actually improved health; and elsewhere that drainage and the cultivation of the soil produced the most serious and devastating outbursts of the disease. Yet again, malaria was found not only in swamps, but also often on hills and dry sandy deserts. Some jungle-covered land was singularly free from malaria: other jungle land was intensely malarial. In fact, malaria existed on soils of every conceivable variety, of every age in geological time. It was impossible to point to any mineral, chemical, or vegetable condition essential to its presence. It was, and had been for hundreds of years, a dark, inscrutable mystery.

Sir Ronald Ross's genius changed darkness to light, and inaugurated a new era in tropical colonisation. To many, of course, the discovery that malaria was carried by mosquitoes merely confirmed them in their pessimism that the control of malaria was beyond human effort. They were wrong; and briefly I give two examples of what has been done in the Malay Peninsula in the past twenty years under different physical conditions. I would premise that the places of which I speak are within three degrees of the equator, have a rainfall round about 100 inches a year spread throughout the year, that the country as a whole is naturally covered by an ever-green damp jungle, and that mosquitoes exist in myriads at all times. One example is of malaria on low-lying land; the other of malaria on hill land.

CAREY ISLAND.

Twenty years ago or less, if the tropical sanitarian had been asked what was the class of land least likely ever to be freed from malaria by the control of mosquitoes (or by any other means for that matter), he would unhesitatingly have named the low-lying coastal land, with high ground-water, heavy clay soil, liable to flooding from the sea. He could easily have justified his choice. Such land had ever been known to be pestilential almost beyond description; it had given rise to innumerable speculations on the cause of malaria—the decay of coral, the mixing of fresh and salt water, to name but two. In every part of the tropical world examples of the deadly power of malaria in coastal regions could be given. In the Malay Peninsula and Archipelago, for example, the Governor, Sir Frank Swettenham, in 1901 ordered the new port called after himself to be closed, so overpowering was the malaria. On the opposite side of the Straits of Malacca, the port Belawan in Sumatra was so malarial that the Dutch left it every night, retired to a town some twenty miles inland, to return by the first train the following morning. Many other examples could be given.

Carey Island is situated on the coastal belt of such land. It is, indeed, an island just above sea-level in its highest parts, and obviously has been formed by the alluvium from the hills. Surrounded by water, on one side by the sea, on others by large rivers or riverine estuaries, containing salt water, it is fringed by mangrove swamps and covered by dense virgin jungle. Throughout its length and breadth it was swamp, either of fresh water or salt.

In 1906, a pioneer planter of Malaya, the late Mr. E. V. Carey, took up a concession of 30,000 acres on the island and began the planting of rubber and coconuts. The island was bunded and drained. Tide gates were necessary. Enough was known of the control of malaria to enable the labour to be kept free from malaria from the first, and opening rapidly proceeded. To-day some 14,000 acres (or roughly 20 square miles) are under cultivation. No European —of a population of from 20 to 30—has contracted malaria on the island since 1912. In 1922 the average Asiatic population was 4344. There were 26 cases of malaria, 14 clinical cases, and 12 in which parasites were found. This is a rate of 6 per mille. The lowest rate recorded in Panama was 14 per mille. There were at the end of last year 962 children, of whom 9 or 0·9 per cent. had enlarged spleen. In about all, but not absolutely in every case, both adult and child, there is reason to believe the infection had been contracted elsewhere. Steps are now being taken to end the last possible source of malaria, namely the disused and neglected wells in the small private gardens of the coolies. When these are properly supervised, I am convinced malaria contracted on the island will be as unknown as malaria contracted in the centre of London. The death-rate of the labour force in 1922 was 8·2 per mille. This freedom from malaria has been achieved by good drainage and by the selection of suitable sites for buildings. It costs the Estate practically nothing; while the absence of malaria makes the Estate one of the cheapest producers of both rubber and coconuts in the East. This is an example of the control of malaria carried by two species of anopheles, namely *A. umbrosus* and *A. Ludlowi*.

THE CITY OF SINGAPORE.

Following the control of malaria in the coastal regions, a new and apparently even more difficult problem confronted us, namely, malaria on hill land. In the ravines or valleys, when under jungle, malaria was carried by *Anopheles umbrosus*; when the jungle was swept away, when, for stagnant swamps in the valleys, swift clean running streams were substituted, malaria was of even greater intensity; in many places death claiming over 300 out of every 1000 of the population per annum. The mosquito carrier which lived in these streams was *Anopheles maculatus*. It is not my purpose here to detail the various methods by which this malaria has been successfully controlled, even in small rural areas; it has been done at a cost well within the reach of a commercial undertaking; indeed the money spent has been recovered within a short period by the greater efficiency of the labour and a lowered cost of production.

I prefer rather to speak of the excellent work done in the city of Singapore. Prior to 1911 a malaria wave swept over the city almost every year. As will be seen from the chart (Fig. 1), it generally reached its maximum in the month of May. In 1911 I was asked to advise the anti-malaria committee, and drew up plans for the control of malaria in a selected area. The late Dr. W. R. C. Middleton was then Health Officer. For the first two years Dr. Finlayson was seconded for the supervision of the work, which was carried out by Mr. McGee, the engineer engaged

for the purpose. Since 1914 the work has been under the control of Dr. P. S. Hunter, now Health Officer of Singapore. He has extended the area greatly; to him the success of the work is mainly due. Dr. Hunter has also extended the work to the fortified island of Blakan Mati, with great advantage to the garrison. Indeed Singapore has now ceased to be malarial, so far as the troops are concerned. The area under mosquito control is almost six square miles. There are 8¾ miles of concrete channels and

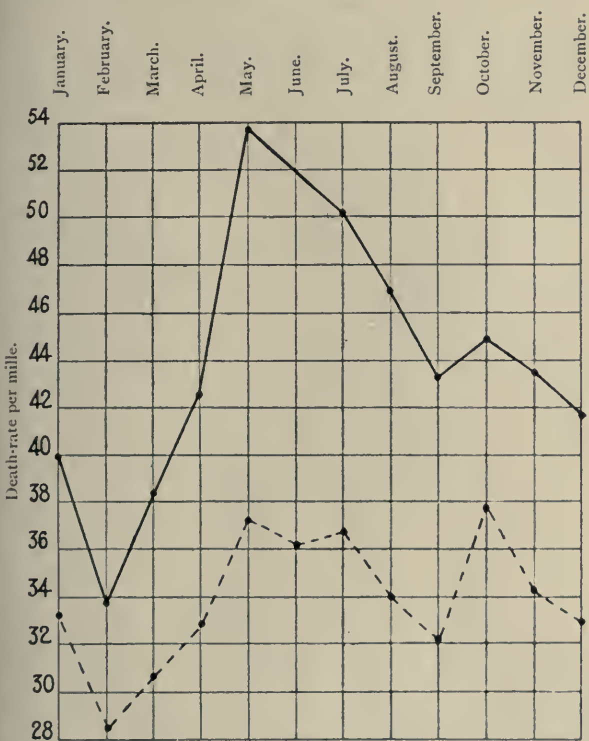

FIG. 1.—Death-rates of city of Singapore.
Average 1903–1912 •——•——•
Average 1913–1922 • – – • – – •

31 miles of subsoil drainage. A sum of approximately 350,000 dollars (say 38,000*l.* sterling) has been spent on capital and maintenance accounts. This year there is a vote of 100,000 dollars (say 12,000*l.*) for maintenance and extension of anti-malarial and general anti-mosquito work.

Further details will be found in the chapter on the "Malaria of Singapore," which Dr. Hunter contributed to my "Prevention of Malaria in the Federated Malay States" (London: John Murray, 1921): see also NATURE, March 16, 1922, p. 334. Following the anti-malarial work, the spleen rate of the children fell progressively from about 50 to zero. The great malarial wave, which raised the death-rate in the month of July 1911 to 85·83 per mille, has been so flattened that the influenza peak of 1918 is now responsible for the highest point. The wave will not entirely disappear until the work in Singapore is completed, and until the surrounding country ceases to dump its sick on the city. Anti-malarial work is being extended into the rural districts by Dr. Scharff.

The peak of the malarial wave in May averaged

	per mille.
for the 10 years 1903 to 1912 . . .	53·76
,, ,, 1913 to 1922 . . .	37·27
a reduction of	16·49

The average annual death-rate from all causes was

	per mille.
for the 10 years 1903 to 1912 . . .	44·11
,, ,, 1913 to 1922 . . .	33·73
a reduction of	10·38

The average population 1913 to 1922 was	312,763
The saving of life is therefore . .	32,214

The saving of life is from all medical and sanitary measures, but the most important is the control of mosquitoes.

Finally, I may add that in the 25 years since Sir Ronald Ross's discovery, more than 100,000 lives have been saved in Malaya alone, owing to that discovery; and the work is just beginning.

The Far Eastern Association of Tropical Medicine meets in Singapore this year. Arrangements have been made to show members over the anti-malarial work in Singapore, and an excursion to Carey Island has been arranged.

Some Consequences of the Gravitational Deflexion of Light.

THE results of the eclipse expeditions of 1919 and 1922 leave little doubt that the deflexion of 1·75″ predicted by Einstein for a ray of light passing close by the sun is a fact. Moreover, as a result of the experiments of Lebedew and Poynting, it is admitted generally that such a ray possesses momentum as well as energy. It does not appear to have been noticed that these experimental results lead to certain important consequences when they are combined with the generally admitted principles of conservation of momentum and of energy.

Let us suppose for the sake of argument that the energy of the ray of light, and consequently also the *magnitude* of its momentum, remains unaltered in spite of the deflexion. Since the *direction* of the momentum has been changed, its component along the real axis of the approximately hyperbolic path has been reversed; if we retain the principle of conservation of momentum for the system sun-light-ray, we conclude that the sun has acquired momentum along the real axis and therefore kinetic energy also. According to the principle of conservation of energy, the energy of the light-ray must have diminished by an equal amount—a conclusion which contradicts the original assumption. Thus we are led to a dilemma: either we must reject one or other of the two principles of conservation of momentum and of energy for the action between the light-ray and the sun, or we must admit that the energy of the light-ray has diminished, as well as its momentum.

It is difficult to imagine a mechanism by which the energy lost by the light-ray is transferred to the sun on the wave theory, though no doubt the pressure of light will play the predominant part, but it is obvious according to the quantum theory. Without entering into details, which must be reserved for a future paper, I may be allowed to refer to one important consequence of the assumption that the light-ray loses part of its energy, namely, that its wave-length is increased by a small amount.

In fact, if the deflexion be δ, the light quantum makes the angle $(\pi-\delta)/2$ with the major axis initially and finally on opposite sides of it. Consequently its loss of momentum in that direction is $(2\nu h/c)\cos(\pi-\delta)/2$, or $(2\nu h/c)\sin\delta/2$ with the usual notation, and this is also the gain of momentum of the sun. Hence the energy transferred is equal to $(2\nu^2h^2/c^2m)\sin^2\delta/2$, where m is the mass of the

sun, and it is also equal to $-h\Delta\nu$, where $\Delta\nu$ is the increase of frequency of the light quantum. Thus $\Delta\nu = -(2\nu^2 h/c^2 m) \sin^2 \delta/2$, and $\Delta\lambda = -c\Delta\nu/\nu^2 = (2h/cm) \sin^2 \delta/2$, a value which is independent of the wave-length, at any rate if δ be so.

For a light quantum passing close by the sun we have $m = 2 \,.\, 10^{33}$ gm., $\delta = 1{\cdot}75'' = 8{\cdot}5 \,.\, 10^{-6}$ radian; hence with $h/c = 2{\cdot}18 \,.\, 10^{-37}$ we find $\Delta\lambda = 3{\cdot}9 \,.\, 10^{-81}$ cm., a change which is far too small to be detected by experiment.

If, however, we assume that the negative electron behaves like a very minute gravitating mass, though acting according to a different law on account of its charge, we obtain a connexion with A. H. Compton's recent quantum theory of the scattering of X-rays (*Physical Review*, May 1923, p. 483). Although this theory in its present form does not account for the excess scattering, it is very successful in explaining the small scattering of γ-rays as well as their softening. To this extent it supports the present view of the deflexion of light. I have worked out the orbits of light corpuscles for a gravitating electric charge, but the full discussion of the results and of their bearing on the structure of the electron must be reserved for the paper already referred to.

Suggested Botanical Exploration of the Higher Summits of the Cape Verd Islands.

IT is somewhat surprising that in our much explored world there is still a group of large islands in the Atlantic which in a botanical and probably also a zoological sense may be said to be imperfectly known. For until we know what lives on the cloud-capped summits of islands like Fogo and San Antonio, which attain elevations of 8000 and 9000 feet above the sea, it can scarcely be said that the Cape Verd Islands have been scientifically explored. Surely here would be a good piece of work for an English yachtsman and two or three investigators from Lisbon. Allowing two weeks for each island, the examination of Fogo and San Antonio would only involve about a month's absence from St. Vincent, the assumed starting-place, and a host of botanical and other curiosities would be gathered in the deep ravines and on the uplands of those mountainous islands. With government aid it could be carried out by one of the learned societies of Lisbon.

Fogo is reckoned to be the healthiest of the islands, and it promises to be the most interesting for the naturalist. But whoever goes will have to be prepared for living in damp conditions, as in perpetual fog and mist.

Anything may be in hiding on those cloud-capped uplands. Concealed in the ravines may still survive plants that have become extinct in other Atlantic groups, or which exist only in islands of other oceans or in distant parts of the world, such as the Tree-Compositæ of St. Helena, the Tree-Labiatæ of Juan Fernandez, the Tree-Lobelias of the mountains of tropical Central Africa.

Then, again, American genera, like Clethra, that have died out in the Canary Islands, may still survive in the Cape Verd group, and the same may be said of numerous other plant-types that have died out in other parts of the world, or are almost extinct there. Within the rain-belt of these mountainous islands may still linger remains of once predominant laurel woods and their associated plants, such as are now so characteristic of the Azores, Madeira, and the Canaries.

The most significant features of island-floras are presented in their connexions with distant regions, and it is on this feature that are largely based the hopes of important results arising from the examination of the summits of the mountainous islands of the Cape Verd group. Thus, Tree-Lobelias link Hawaii in the Pacific Ocean with the highlands of Kilimanjaro in tropical Africa; the islands of Bourbon and Mauritius in the Indian Ocean possess species of Acacia trees that are scarcely distinguishable from a tree common in the Hawaiian mountains. So again the affinities of the endemic genera of Juan Fernandez connect its flora with St. Helena, the Canary Islands, and the Chatham Islands. The distant connexions of the endemic genera of the Socotran flora are equally remarkable. They cover much of the globe and are found in Asia, Africa, and America.

As Hooker urged in his lecture on insular floras, islands have frequently served as sanctuaries for plant-types that have become extinct on the continents, and in the same way we would expect the Cape Verd Islands to harbour the kith and kin of many plant-types that have failed in the struggle for existence in distant parts of the world.

We cannot afford to let slip opportunities of this kind for increasing botanical knowledge. The island of Fogo has probably already lost much of its original flora through the agency of the woodcutter, and not many trees remain. Barker-Webb, Hooker, Schmidt, Krause, Vogel, Christ, Hemsley, and Coutinho have done much to elucidate the plant-history of the Cape Verd Islands, but the most interesting features of their flora may be not yet disclosed.

Polar Temperatures and Coal Measures.

I THANK Mr. Bonacina for his sympathetic comment in NATURE of September 22, p. 436, on my letter on "Polar Temperatures and Coal Measures" and for the added clarity he has brought to this subject. He mentions disagreement with me on one minor issue only, and that relating to the south polar regions. In that connexion I am glad of the opportunity to confess that my thinking on the subject of polar coal measures has really been based almost exclusively upon my knowledge of the Arctic. My suggestion that similar conditions might explain Antarctic coal was a sort of parenthetical remark made without any special consideration of the Antarctic problem.

Mr. Bonacina says: "I do not, however, fully support Dr. Stefansson in expecting that a lowland south polar continent surrounded by an ice-chilled ocean would be liable, at least so often, to the high summer temperature of the Arctic lowlands." A reading of Mr. Bonacina's letter in comparison with mine will show that this partial disagreement is apparent only, due to my faulty expression. I did not mean to say that if the postulated low Antarctic continent were somewhat larger than the actual present continent, high temperatures would be as frequent there as they would be in the Arctic if the land masses of North America and Asia were connected across the North Pole by continuous low land. All I meant to say was that such a hypothetical low southern continent might have temperatures high enough for the development of a coniferous forest.

Mr. Bonacina gives the explanation which I have supposed correct for the lowering of summer temperatures in the northern Mackenzie valley by almost continuous winds blowing from the north.

He suggests that such winds would be even more persistent in the hypothetical southern continent. In that connexion we must remember that in spite of the northern cold summer monsoon the Mackenzie coniferous forest does extend more than 150 miles north of the Arctic circle, and indeed north of the southern limit of the maximum "tides" in the Mackenzie (by tide we here mean the rise of five or six feet in the eastern Beaufort Sea caused occasionally by westerly gales. The tide, proper, is less than one foot).

No such extremes as the occasional Arctic +95° F. are necessary for the prosperity of conifers. Mr. Elihu Stewart, the Forestry Commissioner of Canada, put on record in the publications of his department (in 1907 or 1908) that he had seen trees 100 feet high more than 100 miles north of the Arctic circle in the Mackenzie delta. Trees above 75 feet in height abound forty or fifty miles farther north. I do not know of any systematic temperature observations taken in the Mackenzie delta at the approximate northern limit of the conifers, but I suppose that 70° F. in the shade is there exceedingly rare. I should judge then that any hypothetical conditions in the Antarctic considered adequate to produce maximum temperatures of 75° F. (even though rarely) would give an adequate heat factor for coniferous forests.

Can the Geostrophic Term account for the Angular Momentum of a Cyclone?

IN meteorological discussion it is sometimes implied that the rotative velocity of the air comprising a cyclone is primarily accounted for by the geostrophic term in the equation of motion.

If considerations of a second order of magnitude be ignored this hypothesis is capable of simple treatment in its main features and is worth examination. Imagine an initial circulation round an axis, of any magnitude whatever, and consider an elemental mass δm at distance r from the axis.

The radial velocity of this element is then denoted by dr/dt taken positive outwards.

The increase in the angular momentum of δm about the axis in time δt due to the geostrophic term is

$$2\omega \sin \phi \,.\, r \,.\, \delta m \,.\, \delta t \frac{dr}{dt},$$

taken positive clockwise in the Northern Hemisphere.

In the limit this becomes $\omega \sin \phi \,.\, \delta m(2r \,.\, dr)$, or $\omega \sin \phi \,.\, d(r^2 \,.\, \delta m)$.

If ϕ be taken as constant, and we sum up for the whole mass of the cyclone, we see that the increase in the total angular momentum in a given time is equal to the product of $\omega \sin \phi$ into the corresponding increment in the moment of inertia about the axis.

The extent to which the moment of inertia can vary is represented by the deepening or filling up of the cyclone, and a rough calculation shows that the possible angular momentum so accounted for is very small, and is, moreover, of the opposite sign to that required by the hypothesis under consideration.

In the above analysis two things have been ignored: (1) The question of the variability of ϕ; (2) the resistance of the earth's surface. If it be supposed that there is a systematic difference between the latitude of the surface inflow and that of the outflow above, there is the possibility of the existence of a term of appreciable magnitude in the case of a large cyclone. On this point observational evidence is weak, and all that can be said is that for a small system the effect must be small, and for large ones we have no reason to suppose it to be large.

The resistance of the earth's surface continually tends to reduce the rotational velocity, and the magnitude of the term concerned is, moreover, large compared with (1), which is of the nature of a differential effect.

On the whole, it seems clear that the angular momentum of a rotating system cannot be accounted for by the geostrophic term, and that its origin must be sought in the initial relative velocities of masses of air subsequently included in the circulation.

L. H. G. DINES.

Benson, Wallingford, August 31.

Zoological Nomenclature: Spirifer and Syringothyris.

IN accordance with prescribed routine, the Secretary of the International Commission of Zoological Nomenclature has the honour herewith to notify the members of the zoological profession that Miss Helen M. Muir Wood, of the British Museum of Natural History, has submitted the generic names Spirifer, Sow, 1816, and Syringothyris, Winchell, 1863, to the International Commission, for suspension of rules, with the view of retaining *Anomia striata* Martin as genotype of Spirifer, and *Syringothyris typa* (s. *Spirifer carteri* Hall) as genotype of Syringothyris.

The argument is presented: (1) that under the rules *Anomia cuspidata* Martin is type of Spirifer, and Syringothyris is synonym of Spirifer: (2) but for seventy years, practically all authors have, in conscious opposition to the rules, taken *A. striata* as type of Spirifer, and *Spirifer carteri* s. *Sy. typa* as type of Syringothyris: (3) so many species are involved in this instance that the application of the rules would present greater confusion than uniformity.

The secretary will postpone vote on this case for one year, and invites expression of opinion for or against suspension in the premises.

C. W. STILES,
Secretary.

Hygienic Laboratory, Washington, D.C.

Colour Vision and Colour Vision Theories.

PROF. PEDDIE states in his letter in NATURE of September 8, p. 362, that the facts that I have given as totally opposed to the trichromatic theory can be explained by it. If he will show how this can be done I can then deal with his explanations. Directly the trichromatic theory is put in a definite form its failure becomes evident. For example, it has been stated frequently by others that the construction of the trichromatic theory given to explain simultaneous and successive contrast will not explain colour blindness, and *vice versa*. There is no fact that directly supports the trichromatic theory. In numerous cases papers written to support the trichromatic theory are found on examination to give facts strongly adverse to it. Prof. Frank Allen has written a number of papers supporting the trichromatic theory. In a paper on the Primary Colour Sensations (*Philosophical Magazine*, vol. xxxviii., July 1919, p. 81) Prof. Allen writes: "But it is difficult to understand why the exceedingly complex region between $\lambda \cdot 470\,\mu$ and $\lambda \cdot 570\,\mu$ should exhibit, as it does, persistency curves with only one elevation in the green." The reader should note that it is only on the trichromatic theory that this region is complex. On my theory it is quite simple and the results should be as stated.

F. W. EDRIDGE-GREEN.

London, September 10.

Transport and its Indebtedness to Science.[1]

By Sir HENRY FOWLER, K.B.E.

PROBLEMS of transportation have been solved more or less successfully in all ages, and some of them, such as the moving of stones to Stonehenge, etc., still excite our wonder and admiration. Such works, and similar ones of much greater magnitude in the East, could be accomplished by quite crude methods if there was unlimited labour available, and if time were of no consequence. The transportation which aids civilisation is that which cuts down the wastage of power to a minimum and reduces the time occupied in carrying this out. It is here that science has helped in times past, and will help increasingly in the future if we are to go forward. In no other branch is Telford's dictum that the science of engineering is "the art of directing the great sources of power in Nature for the use and convenience of man" so well exemplified, and this utilisation has been carried forward at ever-increasing speed during the last hundred years. If we take the definition of science as "ordered knowledge of natural phenomena and of the relations between them," as given by W. C. D. Whetham in the "Encyclopædia Britannica," we shall easily see how transportation has been dependent upon it.

Transport is mainly dependent upon three things—the method of propulsion, the material available for use, and the path over which traction takes place. I propose to confine my remarks to the first two. Advance in traction really became rapid when methods of propulsion other than those of animals and the force of the wind became available. The greatest step forward—wonderful as some of the achievements of aeronautics have been of recent years—came with the development of the steam engine.

Like most great achievements in the world, it was not a lucky and sudden discovery of one individual, although here as elsewhere we associate the work with the name of one man especially. This has usually been the case, and without wishing to detract from the work of the individuals who are fortunate enough to utilise the ordered knowledge available to the practical use of man, one must not forget the labours of those who have sought out that knowledge and have given it freely to the world, thus placing it at the disposal of the one whose imagination and creative faculty were great enough to see how it could be utilised in the service of man.

The first attempt at traction by using a steam engine was a failure because of the lack of this knowledge. I refer to the work of Jonathan Hulls and his attempt in 1736–7 to apply a steam engine to the propulsion of a boat on the River Avon in Worcestershire. He failed because of the lack of that knowledge, although undoubtedly he possessed the necessary imagination.

Although James Watt is not directly associated with traction, it was his application of science to practical use that finally gave the greatest impulse to transportation that it has ever had. No advance had taken place after Newcomen's engine of 1720 until Watt's work of 1769. His knowledge of Black's work at Glasgow on the latent heat of steam, and his own experiments with the Newcomen model, led to the success of his improvements of the steam engine. His scientific knowledge is clearly shown in his patents and publications, for he dealt with steam jacketing in 1769, with expansive working in 1782, and he devised his parallel motion in 1784. His direct connexion with transport includes the reference to a steam carriage and a screw propeller in 1784, while the firm of Boulton and Watt corresponded with Foulton for a period extending from 1794 to 1805.

Although Cugnot in 1770 and Murdoch in 1786 had made models of vehicles propelled by steam, it was Richard Trevithick with his steam carriage in 1801 and 1803 and ill-fated railway in 1804 who first showed the practical application which could be made. It is probable that the engine which his assistant, Steel, took to the wagon-way at Wylam in 1805 turned the thoughts of George Stephenson to the work that has meant so much for us.

No one can read the early life of the "father of railways" without appreciating that he was from young manhood a searcher after scientific knowledge. The advances he gave to the world of transport were all due to his practical application of the knowledge he had obtained himself or had learned from others. It is so often thought that because the early inventors and engineers of the beginning of last century had not received what we now call a scientific education that they were not in any sense of the term men of science. It must be remembered that at that time the knowledge of natural phenomena was very limited, and it was possible to know much more easily all the information available on a subject than at the present day, when we have such a mass of miscellaneous information to hand on every conceivable subject. It was ordered knowledge which led Stephenson to adopt the blast-pipe of Trevithick. It was the desirability of obtaining ordered knowledge that caused him to carry out those experiments which showed to him the advantages of using rails, and it was the scientific appreciation of the necessity of increased heating surface that made him adopt the suggestion of using tubes through the water space in the boiler of the "Rocket." His appreciation of the advantages of science was shown by his acceptance of the presidency of the Mechanical Science Section (then as now Section G) of the British Association in 1838, and it is interesting to note that one of the earliest grants in Section G was for a constant indicator (for locomotives) and dynamometric instruments in 1842–43, while Stephenson was still alive.

From the time of Stephenson the progress in propulsion on rails by steam locomotives was steady if slow. The investigations for a long while were largely confined to the question of expansion and condensation, and although the results attained were noteworthy in the case of steamships, on the rail there was little advance in the principle of propulsion, although the improvements in materials allowed a steady growth in power and size. Although work was done by compounding and using higher pressures, the greatest

[1] From the presidential address delivered to Section G (Engineering) of the British Association at Liverpool on September 14.

advance came to steam locomotives by the use of superheated steam. This was no new thing, for Papin in 1705 seemed to have an appreciation of its value. As pressures and the resultant temperatures increased there came difficulties with lubrication. With the increased use and knowledge of mineral lubricants Dr. Schmit was in 1895 able to devise methods of using superheated steam which have been of the greatest use to transport and to the community.

In spite of the fact that the idea of the utilisation of steam for giving rotary motion is old, its commercial adaptation in the turbine is modern. Rarely, if ever, has there been such a direct and instantaneous application of science to practice. We are too close at present to the matter to realise what a change has taken place in the world owing to the introduction of the steam turbine. One realises the work done by De Laval, Curtiss, Rateau, and the brothers Ljungstrom, but the name which will always be associated with the steam turbine as firmly as that of James Watt is with the inception of the steam engine is that of Sir Charles A. Parsons. The success of his work is due to his application of scientific principles to the many points of the turbine and its accessories. Apart from its application to marine work, it has made possible the economical production of electrical energy, which is doing so much, and will do so much more in the future, for rail transport.

The last means of propulsion that I can deal with is the internal-combustion engine. This, as we almost universally have it to-day, is the result of the cycle adopted by N. A. Otto in his gas engine in 1876. Here again the engines we have are the result of careful and studied investigation, and the advance made has been so much more rapid than in the case of the steam engine and electrical machinery because of the more advanced state of scientific knowledge.

In relation to transport the work has proceeded on two distinct lines, the Daimler and the Diesel engines. In 1885 Gottlieb Daimler produced the engine associated with his name, which utilises a light spirit supplying a carburetted air for the explosive mixture for the cylinder. The development of this engine has itself proceeded in two directions. In one it has been made very much more flexible and silent in its adaptation to motor-car work, while in the other the great desideratum has been lightness and in association with the improvements in the necessary materials has rendered possible the aeroplane as we have it to-day. In both cases the development to the degree reached has been due to a careful study primarily of the pressures, compression, and composition of the mixture.

The Diesel engine was invented in 1894 by Rudolph Diesel, and works by the injection of oil or pulverised fuel into the engine cylinder. Its development has taken place both on the four- and two-stroke cycle, and although considerable progress has been made with land engines, it has been used chiefly for marine transport.

The internal-combustion engine has not been largely used for rail transport owing to its comparatively high cost of fuel per horse-power and its lack of flexibility. The latter is particularly the case when one remembers the high torque desirable, which can be attained in both the steam and electric locomotives in starting.

The early efforts of Hulls have been mentioned, and it was only natural that the work of Watt on land should be followed by application of the new power available to propulsion on the water. Although the growth after the work of Symington, Fulton, and Bell may have seemed to be slow, it was continuous, and constant experiments and research were made both in marine engines and in their application. Saving of fuel has played a much more important part here than with the locomotive, and since more space was available and greater power required, the advantages of the expansion of steam were rendered more imperative and had greater scope than in the other long-established method of mechanical transport. The great advance came with the turbine, and it is interesting to notice that whereas in early days engines were geared up, most of them now are geared down to the screw. Scientific methods have been applied to all those details of measurement and experiment that have led to transport by sea being carried on at increased speed and with decreased cost per ton carried. The application of liquid fuel and the introduction of Diesel engines, both with the object of increasing the space available for cargo, have been carried out on true scientific lines.

Of transport by road it may be said that its commercial inception came at a time when scientific knowledge was well advanced, and its progress was in consequence more rapid. The development of the motor-car engine is a case of the careful application of the fundamental principle developed with ever-increasing care until we get engines as noiseless, as efficient, as trustworthy, and as flexible as we have them to-day.

Much could be said of the indebtedness of aeronautics to science, but I will only speak of the aeroplane. It was not until the development of the internal-combustion engine that the matter became really practical. The War was naturally a great incentive to the advancement of our knowledge of aeronautics. In the means of propulsion, research has given an engine of such size and so light in weight per horse-power that what was a laboured struggle against the effects of gravity has changed into the ability to rise at considerably more than 1000 feet per minute to heights where the rarefaction of the atmosphere renders it necessary for oxygen for breathing to be obtained artificially. The safety of flying as the result of the work of Busk has rendered the machines stable even in such a medium as the air. There is no greater example of the indebtedness of transport to science than the rapidity with which the possibilities of transport by air have advanced.

The other point I would deal with in some detail is the question of materials. We, to-day, have no basic metal or material which was not known when transport first turned to mechanical methods for assistance. The change which has come about has been as largely due to the advances made in metallurgy as to the inventions in mechanics that have led to the improvements in means of propulsion and in machinery. The early builders of steam engines were not only troubled through inability to get their engines machined properly, but also with the difficulties of obtaining suitable material for the parts they required. Steel has been known for thousands of years, but its rapid

and economic production is of very recent growth. It has very truly been said that every great metallurgical discovery has led to a rapid advance in other directions. I will as before deal with the railway as an example.

We can scarcely appreciate now the conditions which existed from a metallurgical point of view on our railways when the British Association first met at Liverpool in 1837. Iron—made laboriously, heterogeneous in character and expensive of production not only in money but also, owing to the heavy character of the methods employed, detrimental to the very character of the workman—was the only material available for the various parts of the mechanism of the locomotive and for the rails. However improved the methods of manufacture were, there could never have been a universal development of rail traction if it had depended upon material made in such a way.

The demand was met at the Cheltenham meeting of the British Association in 1856 when Bessemer made public the invention he had already been working on for two years, which was to ensure a cheap method of production of a material so essential to transport. One should also mention with Bessemer the name of Mushet, whose work helped so materially in getting rid of the red shortness which in the early days gave such trouble. We are apt at the present day to belittle somewhat the work of Bessemer in view of the more improved methods now employed, but his name must for ever stand out as the one who made cheap transport possible. After the use of manganese in one form or the other as a deoxidiser and a "physic" for sulphur, there remained, however, the baneful effect, due to phosphorus, which prevented the use of the ores of more general occurrence. There have been few more epoch-making announcements made at meetings of technical subjects—although this was not appreciated at the time by many of the audience—than S. G. Thomas's announcement of the discovery of the "basic" process, which he made at the meeting of the Iron and Steel Institute in March 1878. His work, associated with that of his cousin, Gilchrist, was the result of close scientific research.

Another investigation which has given great results in transport has been the ever-growing use of alloy steels. For the scientific inception of these we owe a great debt to Sir Robert Hadfield. His first investigations materially affect transport to-day. Mushet had previously worked on self-hardening tool steel containing tungsten, but the work was only carried out on a small scale. In 1882 Hadfield had produced manganese steel. This is a most remarkable product with its great toughness, and is extensively used for railway and tramway crossings, where resistance to abrasion is of great value. This was the first of a remarkable series of alloys which have made possible the motor car and the aeroplane as we have them to-day.

Continuing his investigations, in 1889 Hadfield produced the compound of iron and silicon known as low hysteresis steel. Indirectly, this is of the greatest interest from a transport point of view, for when used in transformers it not only reduces the hysteresis losses, but also allows of a considerable saving in the weight of core material.

From these early uses of alloy steels there has grown up a large number of alloys, many of which are of the very greatest use for various transport purposes. It is not too much to say that the modern aeroplane is the result of the material now at the designers' disposal both for the engine and for the structure itself. The strength of some of the chrome-nickel steels combined with their ductility is extraordinary, and is due not only to the composition of the metal, but also to the results which have been obtained by patient scientific investigations relating to their heat-treatment. Taking one other example, one may quote the use of high chrome steel—for the early investigations into which we owe so much to Brearley, and to its later developments to Hatfield also—for the valves of aeronautical engines, subjected as they are to high temperatures. At one time it looked as if the advantages which follow high compression and its resultant high temperature might be lost owing to the inability of ordinary steel to resist this heat, but the employment of 13 per cent. chrome steel allowed work in this direction to be continued.

It is not only with steels that we have been benefited so much from research. The case is as marked with light alloys, which have aluminium as a base. The latter itself is the result of investigation along scientific lines, and in aeronautical work particularly much has been done towards giving a metal both light and strong by the work of Walter Rosenhain, F. C. Lea, and others.

It may be said that all I have dealt with up to the present has been the result of special investigation, and that "ordered knowledge" is not of assistance to an everyday engineer. The results I have obtained with the assistance of my colleagues, especially L. Archbutt and H. A. Treadgold, dealing with the solid locomotive crank axle are of interest in this connexion. Not only is the axle subjected to stresses set up by revolving it while it is loaded with the weight of a portion of the locomotive on its axle-bearings and by the steam pressure on the pistons transmitted to the crank-pins, but it has also to withstand the shocks set up by its running on the rails, which cannot be calculated. For about twenty years we have endeavoured to get the knowledge we have obtained into an ordered state, from observation and discussion with the metallurgists attached to the various manufacturing firms. Certain points are obvious, such as the necessity of a good micro-structure, and we can with confidence say that the steel "shall be as free as possible from non-metallic enclosures, and that the micro-structure should show uniformly distributed pearlite in a sorbitic or very finely granular or lamellar condition and be free from any nodular or balled-up cementite. It must also be free from any signs of segregation and from any coarse or overheated structure." (Extract from Midland Railway specification for crank-axle forgings.) Toughness rather than strength is required, and the studied consideration of these points has led to an increased life in miles of the crank axles of the 3000 locomotives owned by the Midland Railway Company, in spite of the fact that they have been constantly growing in size, in pressure on the pistons, and in the work expected from them.

It will be appreciated that the above result, which

is unquestionably the result of "ordered knowledge of natural phenomena and the relation between them," is only one example, if perhaps the most marked one, in our experience. A somewhat similar record could, however, be written on locomotive tyres and other matters.

I think I have shown adequately the debt which transport, as well as other branches of our profession, owes to the study of "ordered knowledge." That in the future this will be even more marked than at present, one can say without fear of contradiction. Not only so, but there must be more and more interdependence between science and engineering. More and more as we advance in the knowledge of natural phenomena will the necessity of the practical application of this knowledge on a large scale become necessary, to confirm it and to bring out fresh features.

The Influence of Science on Christianity.[1]

By Canon E. W. BARNES, F.R.S.

IT is a commonplace that all religions, even though their formularies and sacred books seem to guarantee absence of change, are constantly modified. Unless religion is moribund it is dynamic and not static. It is a living process within the spirit of man; and, as such, it is profoundly affected by the ideas and emotions of the community in which it exists. Religious thought and feeling alike are influenced, for good or ill, by contemporary political, social, and intellectual movements. During the last century there has been a movement of human thought as influential and as valuable as that of Renaissance humanism. The assumptions and methods of science have affected the whole outlook of educated men. In particular, those branches of science which are concerned with the domains of physics and biology have radically changed our conceptions both of the structure of the visible universe and of the development of life upon this earth.

The effect of the scientific movement, alike on organised religion and on private faith, has been prodigious. In any circumstances it would have been far-reaching. But unfortunately, representative Christian leaders, with the eager support of their communions, opposed the new scientific conceptions as they appeared. Science was then compelled to fight for autonomy on its own territory; and, as Dr. Hobson says in his recently published Gifford lectures, the result has been a prolonged struggle "in which theology has lost every battle." As a consequence it is now widely believed by the populace that Christianity itself has been worsted.

At least a generation must pass before it is generally recognised that, with regard to religion, science is neutral. Educated men know that the traditional presentation of the Christian faith must be shorn of what have become mythological accretions. But Christianity resembles a biological organism with a racial future. In the struggle for existence it gains strength and power by utilising its environment. It seeks both freedom from old limitations and increased mastery of hostile forces. Amid all change its essential character is preserved, for it rests on historical facts combined with permanent intuitions and continually repeated experiences of the human spirit. The great pioneers, whether in science or religion, are few. Men usually accept both scientific and religious truth at second-hand. The expert speaks with the accent of what seems to us to be unmistakable authority. We make such imperfect tests as we are able to apply to his teaching; and perforce rest content.

We must never forget that all human activity, and not merely those aspects which we call science and religion, rests upon unproved and unprovable assumptions. The existence of such assumptions is often ignored. They are there, none the less. Often lazily and hazily we conceal them under the term "common-sense." Faith, however, is a necessity of existence. Zealots sometimes have contended and still contend that there is a moral value in blind faith. But the modern world, so far as it has fallen under the sway of scientific method, demands that faith shall be reasonable and not blind.

In science we build upon the assumption that the processes of Nature can be represented by schemes that are, to us, rational. There is, we postulate, a unity between Nature's processes and the working of the human mind. The address given this year by the president of the British Association shows how extraordinarily fruitful this assumption has proved to be. But, when we consider the vast domains of science which still remain to be explored, we must grant that the rationality of the universe remains a postulate of reasonable faith. As we pass from science to philosophy and religion, we have to assume the existence of a universal Mind in order to bind together the sequences of phenomena which science observes and describes. Then, as the basis of religious faith, we further assume that the values, which we instinctively deem supreme, express the quality of this Mind to whom all natural process is due. We thus assert that goodness, beauty, and truth are not private values of humanity, but attributes of God.

The different processes of the human mind, thought, will, and feeling, cannot be decisively sundered. As a consequence, the search for truth made by men of science has in our own time profoundly affected our religious outlook. Science has not merely created a new cosmogony against which, as a background, religion must be set. But, as the character of its postulates and the extent of its limitations have become more clear, science has given us a new conception of what we mean by reasonable faith. In so doing, it has strikingly altered the way in which we approach religion. Some old modes of argument and their attendant dogmas have rapidly become obsolete. A great gulf has opened between constructive and merely defensive types of theology. Among religious communions there is, in consequence, much confusion, some bitterness, fear of change combined with recognition of its necessity. The direct influence of science

[1] From a sermon preached in the Lady Chapel of Liverpool Cathedral on Sunday morning, September 16, in connexion with the visit of the British Association to the city.

and its more obvious triumphs are known to all. The earth is not the centre of the universe; its age must be measured by hundreds of millions of years; man upon it is the derivative of lower forms of life. No orthodox theologian, in classical or medieval times, held or would have dared to assert such facts. Henceforth they must find their place in any dogmatic scheme of faith.

The indirect influence of scientific method, its patient induction, its readiness to admit divergent conceptual representations of observed facts, its absence of exaggeration, its hostility to evasive language, and, above all, its abhorrence of argument which pretends to be free but is pledged to reach assigned conclusions—this influence has not yet made itself fully felt. Theological thought, which claims to be scientific and is still widely accepted, preserves bad traditions. The work of the best contemporary theologians is free from blame. But to any one familiar with the scrupulous honesty of modern scientific research the dogmatic inconsequence of much current religious apologetic is painful. For this reason young men and women, who have had a scientific training at our universities, often complain bitterly that they cannot get adequate religious teaching. They have no more desire for undogmatic religion than for hazy science. But they demand that religious dogmas shall be taught with the same frankness, the same readiness to admit progress through change, the same absence of elaborate and unnecessary complication as they are accustomed to get in scientific instruction. Especially do they resent the use of archaic language, which they suspect, not always unjustly, to be used as a cloak beneath which awkward problems are concealed. As the influence of the methods of scientific investigation increases, the dissatisfaction to which I have alluded will spread. There is only one way in which accredited religious teachers can overcome it. They must use scientific method. They must avoid, whatever the cost, the snare of obscurantism.

At the present time we suffer from what I feel forced to regard as an unfortunate development in the religious history of England. A century ago the dominant type of English religion was evangelical. The language used had at times the over-emphasis which is common in devotional literature; but men spoke of realities which they had experienced. That their convictions were genuine, their good works abundantly showed. Their faith was a power. Unfortunately it was joined to a cosmology which was fated to be destroyed by the progress of science. The ravages made in their scheme by geology were already ominous in the year 1823. The faith, it was felt, was in danger. Wisdom pointed to the acceptance of new scientific truths. But it is given to few to "greet the unseen with a cheer." So the Tractarians, the religious reformers who then arose, men of piety and ability, turned to the past for safety. The system which they embraced not only contained the cosmology now repudiated by educated men, but was also a synthesis of religious ideas of pagan origin combined with philosophic concepts now obsolete. English religion is still struggling with this burden: and, as I see the matter, no healthy reconciliation between science and organised Christianity is possible until it is cast aside.

Men of science can do much to help the community during the period of transition through which we are now passing. Their reverence for truth can be made an inspiration of especial value to pious souls. Among men of science there is the moral austerity without which the finest intellectual work is seldom, if ever, achieved. During the last generation, moreover, they have shown a steadily increasing sympathy with religion, an enhanced appreciation of the unique power of Christianity, at its best, to serve the human race, to foster spiritual progress while preserving spiritual freedom. I would urge all men of science whom my words may reach to take every opportunity to set forth their religious ideals, to show how, in their own minds, Christianity and science interact. Personally I think it unreasonable to demand that their language should be orthodox. The great master to my thinking is Hort, the only theologian of the nineteenth century who began with a thorough scientific training; and Hort said progress in theology must come "by perilous use and perilous reform." A faith worth having needs no artificial protection. Individually each one of us may make mistakes: in the end truth will prevail through honest argument. The religious sincerity of able men with trained minds is of value in itself; and, I am convinced, the essentials of Christianity will survive by their own inherent strength.

The Swiss National Park.[1]

By Prof. C. SCHRÖTER, Federal Technical High School, Zürich.

SELDOM has a movement of a purely idealistic character spread so rapidly and victoriously through the world as the movement to protect Nature against the civilisation which threatens to overwhelm it. Everywhere is heard the cry, "save, what may yet be saved, of the original face of mother earth."

Many are the tasks of those engaged in this movement: the preservation of natural geological monuments and prehistoric sites, the protection of rare plants, fine old trees, interesting plant-communities (*e.g.* those of moorland, steppes, or dunes), and the prevention of the extermination of animals. But most effective and profitable of all is the creation of Nature reserves where landscape, plants, and animals alike being protected from the encroachment of man, the sway of Nature is paramount. Such areas may be called "Complete Nature Reserves" or, to borrow an American term, "National Parks."

In 1906 a movement arose in the Schweizerische Naturforschende Gesellschaft, which resulted in the formation of a Commission for Nature Protection, with Dr. Paul Sarasin, of Basel, as president. This

[1] For the translation of the original manuscript the author is much indebted to Prof. R. H. Yapp, University of Birmingham.

Commission, which consists of geologists, botanists, zoologists, and archæologists, serves as a co-ordinating centre for the various efforts for Nature protection throughout Switzerland. Local sub-commissions have been appointed in all the Swiss Cantons, which suggest, for their respective Cantons, local laws for Nature protection. Already the Commission has secured the preservation of about 400 erratic blocks and 50 trees of special interest; further, some 13 moors, lake margins, bird sanctuaries and nesting-places have been

FIG. 1.—The Scarl Pass near Schembrina; in the background Murtèra la Tamangur (2998 m. above sea-level). The wood consists of larch and *Pinus cembra*.

FIG. 2.—Piz Linard (3414 m. above sea-level), seen from Zernetz. (This mountain is not in the National Park, but one of the finest sights from the Park.)

declared protected areas. The chief work of the Commission, however, has been the creation of a Swiss National Park. After many attempts an area of about 140 sq. kilometres in the Ofen district of the Lower Engadine was secured (between the years 1909 and 1914) as a Complete Nature Reserve.

FIG. 3.—Timber line at Munt la Schera. (Larch and *Pinus cembra.*)

This district is peculiarly suitable for the purpose for the following reasons: Its mean elevation above sea-level is considerable, in consequence of which the snow line lies as high as 3000 metres and the alpine tree limit at 2300 metres. Alpine life, therefore, can be widely distributed within the area. In wildness and naturalness, as in loneliness and seclusion, it is scarcely surpassed anywhere in Switzerland. It is very sparsely populated, so that the prohibition of forestry and grazing operations involve but little hardship for its human inhabitants. It possesses extensive forests, of which the 2600 hectares of dense forest of the erect mountain pine (*Pinus montana*, var. *arborea*) deserve special mention. There are also magnificent forests of *Pinus cembra*, mixed woods of spruce and larch (*Picea excelsa* and *Larix europaea*), a peculiar mountain race of Scotch fir (*Pinus sylvestris*, var. *engadinensis*), and extensive areas occupied by the creeping mountain pine (*Pinus montana*, var. *prostrata*). In addition to the great abundance of conifers there is also a rich herbaceous flora, the great variety of geological substrata rendering possible the existence of both calcicole and calcifuge plants. The dividing line between the floras of the western and eastern alps passes through the region. In the National Park there is, therefore, a mingling of eastern and western forms, many eastern species occurring, so far as Switzerland is concerned, only in this district. Animal life, too, is abundant, chamois, marmots, deer, foxes, black game, golden eagles, etc., enlivening the landscape.

The greater part of the National Park is leased by the State from the owners of the land for a period of ninety-nine years, the State alone having the power to terminate the contract. The State has further pledged itself to contribute a sum not exceeding 30,000 francs per annum for the rent of the Park. Human interference is absolutely excluded from the whole region. Hunting, fishing, manuring, grazing, mowing and wood-cutting are entirely prohibited. No flower or twig may be plucked, no animal killed and no stone removed; even the fallen trees must remain untouched. In this way absolute protection is secured for scenery, plants, and animals; Nature alone is dominant. Any one may visit the Park, but only simple alpine shelter huts are provided—no hotels are allowed to be erected. Camping and the lighting of fires are prohibited. The custodianship of the Park is entrusted to four resident keepers.

FIG. 4.—Alp la Schera with Munt la Schera (2588 m. above sea-level).

The Schweizerische Naturforschende Gesellschaft has undertaken to carry out a thorough scientific investigation of the National Park, and its Scientific Park Committee is now engaged on this work. The initial task is the preparation of complete lists of species inhabiting the reserve. Further, by means of exact surveys of selected areas, repeated from time to time, it is hoped to study—as the previous influence of man

and his domestic animals becomes more remote—the gradual restoration of the original flora and fauna, the re-conquest of pasture by forest, and so on. By the work of successive generations of investigators, it will be possible to follow the truly natural successions and changes occurring within the area, and to study in detail the natural relations between soil, climate, and organisms. The safeguarding from interference by man and beast will also be utilised to study the slow secular changes of land and water. In this unique laboratory, the naturalists of Switzerland will find themselves united in a common work. Maintenance expenses, such as the wages of the four park keepers and the upkeep of roads and huts, as well as the cost of the scientific investigations, are provided by the Schweizerische Bund für Naturschutz, an association which at the present time numbers more than 30,000 members.[2] Thus the Swiss National Park is a commonwealth in which alpine Nature can recover and develop undisturbed: a refuge, a sanctuary for plant and animal life. It is an island of primeval Nature, unaffected by the devastating waves of human civilisation which break about its shores. During visits to this Nature reserve one cannot fail to be impressed by the grandeur of the scenery and the wealth of plant and animal life. But still deeper is the feeling of patriotic pride that a whole nation is pledged to preserve this fragment of primitive Helvetia, unexploited for purposes of material gain, as a heritage for generations yet unborn. It is a piece of idealism especially valuable in this materialistic world.

[2] The annual membership subscription is 2 francs, life membership 50 francs. Foreign members are welcomed; any one wishing to join is invited to communicate with Dr. St. Brunies, Sekretär des Naturschutzbundes, Basel, Oberalpstrasse 11.

Obituary.

Dr. E. F. Bashford, O.B.E.

An outstanding figure in cancer research has been removed by the death, from heart failure, of Dr. Ernest Francis Bashford. After a most distinguished medical career at the University of Edinburgh, he pursued laboratory investigations in Germany, especially under Ehrlich, and became assistant to Sir Thomas Fraser in pharmacology. Even in the short time he spent in that laboratory, he enriched pharmacology by a memorable contribution on the antagonism of atropine and morphine.

When the organisation now known as the Imperial Cancer Research Fund was started in 1902, the committee appointed Bashford as general superintendent and director of the laboratories. So well was the confidence of the committee justified that in a few years his researches were known all over the world, and the laboratory, housed originally in the upper floors of the College of Surgeons' hall on Victoria Embankment, was recognised by all as the leading institute in the world for the experimental study of cancer. The position achieved was the outcome of intense work by a brilliant staff of colleagues inspired and directed by a forceful, imaginative, and tireless personality. The memorandum of proposed research submitted to the committee by Bashford at the commencement is still on record and demonstrates how surprisingly he, a young man with little previous acquaintance with the problems and quite inexperienced in the responsibilities of an institute, had grasped the essential fact that cancer must be studied as a problem in comparative biology. The exact statistical investigations of cancer in human beings in Great Britain and the collection of reports of its occurrence in civilised and uncivilised races early occupied his attention, and his writings proved convincingly that the incidence of the disease could not be correlated with many of the factors that impressed, and still impress, the imagination of the uninitiated. When there was added to this the study of the zoological distribution of cancer, the insistence on the breadth of the problem became obvious.

The first real advance in the biological study originated from the discovery by Jensen of the transplantability of a mouse carcinoma. The avenues thus opened up were enthusiastically explored, and there followed in rapid succession contributions dealing with the cytology of malignant new growths, the source of their cellular constituents, the specific reactions of the host, the induction of artificial resistance to growths, the study of refractoriness or susceptibility, the demonstration of the essential similarity of malignant neoplasms throughout the animal kingdom, biochemical investigations of great importance, and a host of other observations over the whole field which may be found in the first five Scientific Reports of the Imperial Cancer Research Fund published under Bashford's direction. Ill-health compelled him to resign his appointment in 1914. During the War he served in the Army in France as a pathologist, and was at the time of his death adviser in pathology to the British Forces on the Rhine. His work marks the beginning of the era of the scientific study of cancer in Great Britain.

ARCHIBALD LEITCH.

Lord Morley, O.M., F.R.S.

Lord Morley, whose death on September 23, at eighty-four years of age, we regret to record, was a great statesman and intellectual leader, the memory of whose work and noble character will long be cherished. As a writer on literary, historical, and biographical subjects, he covered a wide field in a style at once delightful and stimulating, and in the field of public life he preserved the best traditions of sincerity and truth. Though Lord Morley was not directly concerned with scientific research, he was sympathetic towards it, and was elected a fellow of the Royal Society in 1892 under the rule which permits the Council to nominate for election persons who "either have rendered conspicuous service to the cause of science, or are such that their election would be of signal benefit to the Society." He was a trustee of the British Museum, 1894–1921, chancellor of the University of Manchester from 1908 until last March, and one of the first members of the Order of Merit created by King Edward VII. in 1902. Lord Morley was made an honorary LL.D. of the Universities of Glasgow, 1879, Cambridge, 1892, St. Andrews, 1902, and Edinburgh, 1904, and an honorary D.C.L. of Oxford in 1896.

Lady Shaw.

Deep sympathy will be felt by a large section of the scientific world at the bereavement which Sir Napier Shaw has suffered by the death on September 22 of his wife, Lady Shaw, who was well known in scientific circles. Lady Shaw was for some time lecturer in mathematics at Newnham College, Cambridge, and was the author of an original little book entitled "First Lessons in Observational Geometry," published by Messrs. Longmans, Green and Co. in 1904. In this book, a course of observational and experimental geometry was outlined similar to that afterwards adopted in schools on the recommendations of committees on geometry as the best introduction to the formal study of the subject. Lady Shaw took a very active part in many organisations and institutions concerned with education, science, and progressive development generally. She was a member of council of Queen's College, London, and of the Women's Local Government Society. She served on several committees of the British Association, and was the secretary of the Citizenship Committee which has prepared and issued some valuable reports. Lady Shaw was also a member of Council, the Executive Committee, the Education Committee, and the Health Committee of the British Science Guild, and the members of these bodies, as well as all others associated with her, hold her memory in grateful remembrance.

Prof. W. Roser.

Prof. Dr. Wilhelm Roser, one of the directors of the Farbwerke vorm. Meister Lucius und Bruening in Hoechst-on-Main, died at Frankfort-on-Main on May 20. He was an important contributor to the development of the German industry of pharmaceutic products and coal-tar dyestuffs.

Prof. Roser came from an old-known Swabian family; his father, Prof. W. F. Roser, was an eminent surgeon of the University of Marburg, and there W. Roser was born on January 30, 1858. At this University he first studied mathematics, a science to which he devoted his hours of leisure. Afterwards he changed over to the study of chemistry under the guidance of Zincke. After a short stay with Fittig in Tübingen, he returned to Marburg and received his doctorate in 1882 for a research upon terebinic acid. For his studies regarding phthalyl-derivatives he received the *venia legendi* in 1885, and researches concerning pyridine and quinoline derivatives enabled him to clear up the constitution of narcotine, an opium alkaloid.

After his nomination as a professor in 1892, the Hoechst firm engaged Prof. Roser as director of the scientific department of their works, at a time when the German chemical factories, having successfully produced acetanilide, phenacetine and antipyrine, were devoting themselves to the further investigation and production of medicines. Prof. Roser was able to direct this work with success. He took part in the elucidation of the constitution of adrenaline and in the synthesis of rivanol, while in the dyestuff branch he was also very successful. It was his main task to introduce young chemists who had come from the High Schools into the works, to the way of working and thinking necessary for technical practice. Several generations of technical chemists owe him their education. He himself was a taciturn man of keen observation and wide knowledge, highly esteemed by industrial chemists as well as by men of science.

We regret to announce the following deaths:

Mr. Malcolm Fraser, late Registrar-General and Government Statistician of Western Australia, on September 17, aged sixty-six.

Dr. F. J. H. Jenkinson, since 1889 Librarian of the University Library, Cambridge, on September 21, aged seventy.

Prof. R. Pumpelly, formerly professor of mining geology at Harvard University, and for many years on the United States Geological Survey, on August 10, aged eighty-five.

Current Topics and Events.

It would appear that the protests which have appeared in the *Times* and elsewhere against the proposed erection of a wireless station at Avebury have been successful. Sir Charles Oman in his presidential address to the Gloucestershire Archæological Society, as reported in the *Times* of September 14, announced that he had received a letter from Sir L. Worthington Evans, the Postmaster-General, stating that the proposal would probably be dropped. Recent experience has made it clear that existing legislation for the protection of sites of archæological importance is inadequate, while it affords no guarantee in the case of any site which is not scheduled under the Protection of Ancient Monuments Act. In the present instance, it is peculiarly disturbing that Government Departments were concerned in what can only be described as an act of vandalism. During the recent meeting of the British Association at Liverpool, reference was made to this matter on more than one occasion, and before the Association dispersed, a resolution was passed which, while instancing the cases of Holmbury Hill, Avebury, and Lulworth Cove, urged strongly in general terms the extension of the powers which may be exercised in the protection of sites of natural beauty or archæological interest.

The use of pulverised coal is spreading steadily, and at the present time more than 20,000,000 tons per annum is being burnt in the United States and Canada alone, largely in the cement, iron and steel, and glass industries. Also the use of coal in a fine state of division is being considered in connexion with the manufacture of briquettes, low-temperature carbonisation, and total gasification processes, such as producer gas. The most striking progress, however, during the last three or four years has been in the use of pulverised coal for steam generation. Since 1920 some of the largest and the most important power stations in the world have adopted this method

of firing, and we understand that to-day more than 1,000,000 tons per annum is being burnt under steam boilers on the "Lopulco" system, while in the next few months, as soon as plants now in course of erection or conversion are completed, the figure will exceed 2,500,000 tons. The pioneer large boiler plant installation for pulverised fuel is the "Lakeside" station of the Milwaukee Electric Railway and Light Co. on Lake Michigan, 40,000 kw. of which was started up in December 1920. This boiler plant is held to be the most efficient in the world, running all the year round at 85-86 per cent. efficiency. The first large pulverised fuel boiler plant in Europe is now being erected at the Vitry power station, Paris.

JUST forty years ago, on September 29, 1883, Prof. Dr. Carl Duisberg entered the employment of the Farbenfabriken Bayer and Co. in Elberfeld, and the influence he has exerted upon the development of the German industry of coal-tar dyestuffs and pharmaceutical products has made his name renowned throughout the world of applied chemistry. Prof. Duisberg received his doctorate at Jena; he then went to Munich in order to complete his education under Adolf von Baeyer, and at that time laid the foundation of the great friendship which for the future connected him with that eminent chemist and with a large number of his pupils. Shortly after he entered the Farbenfabriken, and succeeded in making essential improvements in the manufacture of substantive cotton dyestuffs. He thereupon became the head of the firm's scientific laboratory, in which he mainly endeavoured to put the purely chemical work on a broader basis than heretofore. At the same time he began to organise the whole business, first by dividing the work of the chemists according to the different kinds and classes of dyestuffs, etc., and then by uniting in one working concern the four principal German firms which make direct cotton dyestuffs. This was the first step in the formation, later on, of the "I.G.," the large concern of German coal-tar dye makers. The site of the works in the narrow Wupper valley of Elberfeld having become insufficient for the rapidly increasing manufacture, it was resolved to build large modern works, and under Prof. Duisberg's direction a magnificent plant was erected at Leverkusen, near Cologne. During the War, after some years of keen competition, the remaining dye-making firms joined this first amalgamation, chiefly through Prof. Duisberg's influence, thus forming one large combine in which the firms preserve their individualities but, at the same time, all proceedings are directed by a uniform programme, and each firm partakes of the profits of the whole concern according to its share in the work. In addition to his activities at the Farbenfabriken, Prof. Duisberg is well known by many other achievements in chemistry, while his great versatility is manifest from the volume containing his essays and speeches published by the Farbenfabriken on the occasion of his jubilee.

THE intellectual stimulus to China of the revolution of 1911 is still manifest by increased scientific and intellectual activity. Despite the political disturbances of the last two years, the scientific institutions are growing in number and usefulness. The Geological Society of China was founded last year, and held its first annual meeting at Pekin in January under the presidency of Dr. V. K. Ting. This year has also seen the establishment of "the China Society of Science and Arts," of which the *China Journal of Science and Arts* is the official organ. It is also the journal of the Shanghai Chemical Society. The fourth number, issued in Shanghai in July (price 2 dollars, pp. 303-424), edited by Mr. A. de C. Sowerby and Dr. J. C. Ferguson, includes an interesting series of papers and notes on scientific and artistic work in China. The articles deal with the Chinese fisheries of Amphioxus, which in places is a food-fish; the Chinese "Mudskipper," *Periophthalmus cantonensis*, which Mr. Sowerby suggests is not merely in the process of evolution to a terrestrial life but may give rise to a race that may replace the higher vertebrates; "The Dragon Mines," by Dr. J. Gunnar Andersson, who describes the ancient Chinese excavations for fossil vertebrates for use as medicine, and also the recent research on Chinese vertebrate palæontology; the war on insect pests, and on the rôle of bacteria; ancient Chinese coins, by E. F. S. Newan; Chinese female names, by J. C. Arlington; Chinese landscape gardening, by Miss Ayscough; a recent exhibition of Chinese pictures; a journey to the Yangtze gorges for photographic work, by H. F. Carey; the dissociation of prehnite, zoisite, and epidote, by E. Norin; the conditions of the Chinese soap manufacture, by Mr. Hsu; and the aborigines of Western China. There are also various reviews and notices of the work of the Chinese scientific societies. The Journal is well illustrated, and deserves the support of all interested in China, as it gives a useful general review of scientific, artistic, and literary work in and in connexion with China.

SIR HUMPHRY ROLLESTON will deliver an inaugural address on "The Problem of Success for Medical Women" at the London (Royal Free Hospital) School of Medicine for Women on October 1, at 3.30 P.M.

THE Research Association of British Flour Millers has been approved by the Department of Scientific and Industrial Research as complying with the conditions laid down in the government scheme for the encouragement of industrial research. The secretary of this Association is Mr. G. H. Ball, 40 Trinity Square, E.C.

THE *British Medical Journal* announces that the Canadian Medical Association is arranging for a Lister Oration to be given once every three years. The first of these will be given next year at the annual meeting in Ottawa by Dr. John Stewart, of Halifax. Dr. Stewart was one of Lister's house-surgeons in the early days of the latter's work in Edinburgh.

ACCORDING to the New York correspondent of the *Times*, a number of fires broke out in many counties of California on September 17, one of which spread to the residential district of Berkeley. Some six

hundred houses were destroyed, including the residence of Dr. B. I. Wheeler, president-emeritus of Berkeley University, but all the buildings of the University itself were saved. The damage is estimated at 2,200,000*l*.

The Institution of Petroleum Technologists is now installed in its new offices at Aldine House, Bedford Street, Strand, London, W.C.2. In addition to a general office, council room, and a well-appointed library, a large room has been fitted up as a members' room. As a house-warming for the new offices, the president and council will receive members and their friends on Wednesday evening, October 3, from 8 to 10 p.m. During the evening scientific apparatus will be exhibited and demonstrated. Admission is by ticket only.

The lectures on recent excavations given during the summer by Miss Claire Gaudet will be repeated this winter on Thursdays, commencing October 4, at the British Museum. The subject, as before, will begin with the earliest known civilisation as shown by the discoveries made within the last few years in Mesopotamia, and will include the excavations at Ur and this year's work at Kish, now known to have been the capital of the first Empire in the world's history, and said to date from about 5000 b.c. The evolution of architecture from these early times until the Roman and early Christian periods, showing the classical influence on all subsequent art up to the present day, will form the basis of the lectures, including whenever possible the arts and crafts of the people. Further particulars may be obtained from the Hon. Secretary, 120 Cheyne Walk, Chelsea.

Sir Arthur Keith, in his annual report on the museum of the Royal College of Surgeons, refers to the completion of the series of exhibits illustrating the principles of pathology. In 1910, Prof. Shattock and Mr. Cecil Beadles commenced to select, arrange, and catalogue specimens. The War interfered with this work; but six further stands were interpolated this year with the noteworthy result that, for the first time, "a complete and systematic treatise on disease has been written, not in words, but in illustrative specimens," and the scope of the pathological section is regarded as fixed. Mr. Cecil Beadles is now in charge of the National War Collection, which will soon be arranged in accordance with an approved scheme. The president of the Royal College of Surgeons of Edinburgh has been given leave to make a selection from War specimens left in store, for the museum of his college. Among notable additions made to the Museum during the past year are a cast of the tooth held by Dr. H. F. Osborn to indicate the existence of a human genus, Hesperopithecus, in N. America during the Pliocene period; a skeleton, probably of Anglo-Saxon date, showing evidence of infantile paralysis, "the earliest trace of this disorder in England"; and the late Celtic remains found at Wortley, Hants, presented by Mr. R. W. Hooley.

Porto Santo, the northern island of the Madeira Archipelago, has a population of nearly three thousand, and the inhabitants have the reputation of being free from dental caries. Dr. M. C. Grabham visited the island recently and examined six hundred natives, twenty-eight of whom were found to be cases of well-established caries. All except seven of these people, however, came from Madeira, and only two of the seven showed the sign which characterises the Porto Santo dentition and is associated with immunity from caries. Early in life, natives of the island develop this characteristic, which consists of a slight yellow band on the upper incisors, and whenever this yellow stain is present, a sound set of teeth accompanies it. The line or band occurs and develops with a regularity which gives evidence of the permeation of the blood fluids in the interstices of the columnar enamel and is associated with an influence protective against the access of caries. Both the stain and the protective influence appear to be derived from the highly mineralised water of the island, the springs of which are rich in chlorides, carbonates and sulphates, in contrast with the sweet waters of Madeira. Dr. Grabham found no scurvy on the island, but many cases of pulmonary disorder. Diarrhœa and alimentary ailments were singularly absent, and the mineralised waters seemed inimical to intestinal parasites. There was no existing instance of malignant disease. Traditionally some cases have occurred, but no form of cancer has taken root at Porto Santo, and Dr. Grabham is inclined to associate this exemption with the simple feeding of the people and with the absence of animal fats, except lard, from the food, and lard is known to be deficient in the vitamin necessary to promote growth and prevent rickets. Food is taken cold; there is no milk or green vegetables, and nothing to involve grinding mastication. The main sustenance is derived from maize boiled with a modicum of lard, with the occasional addition of fish and an onion or two. At the Liverpool meeting of the British Association, where Dr. Grabham described the results of his inquiry, he showed a skull (since deposited in the Hunterian Museum) of a Porto Santo man of about sixty years of age, taken promiscuously from an exposed grave, whose teeth were all sound: and also exhibited many specimens of the soil, the vegetation, and the mineral water with analyses.

Among the forthcoming books announced by the Old Westminster Press is the 3rd edition of "Popular Fallacies" by A. S. E. Ackermann, which contains 696 pp. of new matter, and deals with 1350 fallacies, including the 460 of the 2nd edition.

The Oxford University Press will publish shortly an original work, by Mr. R. T. Gunther, on the instruments used by early men of science, under the title "Early Science in Oxford." The work will be issued in two volumes—one on chemistry, mathematics, physics and surveying, and the other on astronomy. No university is richer in the apparatus and records of bygone men of science than Oxford. Mr. Gunther's illustrated account of her early science is the outcome of a first attempt to direct attention

to those instruments, and to early descriptions of instruments, by which scientific studies in the university have been advanced.

DR. D. H. SCOTT is bringing out through Messrs. Macmillan and Co., Ltd., "Extinct Plants and Problems of Evolution," a volume founded on a special course of lectures given in 1922 at the University College of Wales, Aberystwyth, the object being to sketch, in broad outline, the geological history of the plant-kingdom, in its bearing on the theory of descent. Messrs. Macmillan also announce "Life in Southern Nigeria: The Magic, Beliefs, and Customs of the Ibibio Tribe," by Amaury Talbot, Resident, Nigeria; vol. iii. (Mammalia) of Prof. von Zittel's "Text-book of Palæontology," revised by Dr. Max Schlosser, translated under the direction of the late Dr. C. R. Eastman, by Marguerite L. Engler and Lucy P. Bush, and revised by Dr. A. Smith Woodward; and a new and revised edition of Prof. W. J. Sollas's "Ancient Hunters."

Errata:—In the article on "The Earth's Magnetic Field for 1922," by Dr. Louis A. Bauer, in our issue of August 25, the formula on p. 295 should be given the number (1); the second author mentioned in the fourth paragraph, third line, p. 296, should be Mr. H. Furner instead of Prof. H. H. Turner.

Our Astronomical Column.

THE SOLAR ECLIPSE OF 1922 AND EINSTEIN'S THEORY.—The current number of the Lick Observatory Bulletin, No. 346, contains the results of the observations on the deflexion of light in passing through the sun's gravitational field made during the total solar eclipse of September 21, 1922, at Wallal, Western Australia. The authors, Prof. W. W. Campbell and Mr. R. Trumpler, give all details for this particular research, which represents only a part of the programme of the William H. Crocker Eclipse Expedition from the Lick Observatory. Two very interesting diagrams show at a glance the type of the results obtained. The first of these is a star chart of the neighbourhood of the eclipsed sun containing the 92 stars actually measured for the investigation. The observed relative displacements of the stars are indicated by short lines oriented according to the directions of displacements. The outline of the brighter parts of the corona as well as the limit of the faintest traces of coronal light are indicated. The second instructive diagram shows the observed radial displacements for each star as a function of the star's angular distance from the sun's centre, while for comparison sake a curve is given indicating the values predicted by Einstein's theory. This graphical representation demonstrates the coincidence between the observed and the predicted light deflexions. By arranging the stars in groups according to their distance from the sun's centre the observed relative radial displacements can be seen from the accompanying table.

Group.	No. of Stars.	Weight.	Mean Dist. from Sun.	Obs. Rad. Displ.	Theoretical Rad. Displ.
			°	"	"
1	8	9·09	0·64	+0·64	+0·70
2	11	19·42	1·06	+0·35	+0·37
3	10	20·15	1·40	+0·30	+0·24
4	8	22·41	1·66	+0·16	+0·17
5	9	21·10	1·90	+0·17	+0·13
6	8	24·67	2·00	+0·15	+0·11
7	11	21·32	2·22	+0·08	+0·08
8	13	21·37	2·55	−0·09	+0·02
9	14	22·78	2·97	−0·04	−0·03

It will be noted that the observed radial displacements given in this table are in remarkably good agreement with the values predicted on the basis of Einstein's theory. The authors point out also that even the stars between 1·25° and 2·25° from the sun's centre, which lie entirely outside of any trace of the corona, show the light deflexion well marked, an effect that would be difficult to explain by an extended solar atmosphere.

EPHEMERIDES OF ALGOL VARIABLE STARS.—At the meeting in Rome of the International Astronomical Union in 1922, the representatives of the Cracow Observatory undertook the calculation and publication of these ephemerides. No. 1, containing these calculations for the second half of 1923, has lately come to hand, edited by Th. Banachiewicz. The explanatory matter is printed both in Polish and in Peano's flexionless Latin, the latter being easy to read.

Comment is made on the fact that from the date January 1, 1925, the astronomical day will begin at midnight, which will cause a break of continuity in formulæ that use the Julian day (beginning at noon). To avoid confusion, it is suggested that a new cycle of days be employed for this purpose, the zero date being the midnight at the beginning of January 0, 1801 (Greenwich). This is adopted in the present work, and tables are given to reduce calendar dates to it. Tables are given for 31 stars, including Algol, the adopted elements being corrected by recent observations, made in several cases by J. Gadomski at Cracow. The times of minimum are given to the third decimal of a day (about 1½ minute).

Since all the minima occurring on each day are arranged on the same page and in the same line, it is a very simple matter to draw up a programme of work on any given night.

FURTHER SEARCH FOR INTRA-MERCURIAL PLANETS.—Though we know from the presence of the Zodiacal Light that there is a considerable amount of scattered matter inside the orbit of Mercury, it becomes more and more unlikely with each total eclipse that there is any single body of sufficient size to be separately discerned or photographed. Prof. Campbell and Mr. Trumpler have made a careful search on the large plates (17 inches square) taken for the Einstein problem in the eclipse of September 1922. They embrace an area of 15° × 15°, and show 550 stars, the faintest being of magnitude 10·2. They were compared, star by star, with the comparison plates taken in Tahiti four months earlier. Nothing was detected in the search; it is noted that rapid motion might weaken a planet's image, but, allowing for this, there could not have been any planet as bright as magnitude 8·5 in the region of the plates, unless it was in the denser parts of the corona. Perrine's search in 1908 covered a region 25° × 8½°, but did not reach quite such faint stars as the present series.

Research Items.

MAGLEMOSE CULTURE IN EAST YORKSHIRE.—The discovery of the Maglemose harpoon at the lacustrine deposits at Skipsea has led Mr. A. Leslie Armstrong to examine, in search of further examples of Maglemose culture in Yorkshire, the strata exposed by recent erosion on the Holderness coast. In the September issue of *Man* he describes a number of flint implements found in the course of his exploration. He remarks that " it is significant that when placed side by side with a series of the usual East Yorks artifacts from the surface, these deeply stained examples from the silt and peat beds are as distinctive therefrom in type as they are in patination, and that they can be paralleled in both patina and type only by certain implements of a dark brown and highly lustrous patina found upon one or two restricted areas in the vicinity of Skipsea and Atwick, upon elevated ground, which there is reason to believe represent former islands in the ancient marshland and sites of early occupation."

NEOLITHIC MAN IN PATAGONIA.—In " Habitantes Neoliticos del Lago Buenos Aires " (*Revista del Museo de La Plata*, xxvii. pp. 85-160), Dr. José Imbelloni describes human remains from Lago Buenos Aires—a place far away in the south-west of Patagonia, which must not be confused with the town of Buenos Aires. It would appear that the number of prehistoric skeletons found in Patagonia diminishes rapidly from north to south. The description, therefore, of a number of finds near Lago Buenos Aires, in the south-west, is of special importance. The ten skulls described were found so long ago as 1897 by Dr. S. Roth under constructions called *chenques*—erections consisting of stones heaped over the bodies more or less symmetrically without there being any form of dug graves. A number of these *chenques* occur in the region of the lake in question. Their age is stated to be Neolithic, though the only proof appears to be the absence of metal (other than precious) from the funeral furniture associated with the burial. Neolithic culture it may be, but of what date in time? To the student of the physical structure of the early inhabitants of this part of the world Dr. Imbelloni's brochure will be of interest, for a long and detailed description of the skulls is given. Comparisons with similar remains from further north are also included. Mention is made of some of the prehistoric skulls of the Old World, but, though interesting, it is to be doubted if any real correlation between types and even cultures of the New and Old Worlds is ever really likely to be fruitful.

SURVEYS IN GREENLAND.—The work of the Danish bicentenary expedition to North Greenland under Mr. Lange Koch included important explorations in Peary Land. Some account of this work with preliminary maps appears in an article in the *Geographical Journal* for August. The expedition filled in the surveys of the north coast between De Long Fjord and Cape Bridgman, thus practically completing the general survey of the coasts of Greenland. On the return journey the southern part of Peary Land was explored and surveyed, and the problem of the so-called Peary Channel reported by the late Admiral Peary in 1892 was finally solved. Erichsen in 1907 found that the channel as a seaway did not exist, but Mr. Koch has now discovered the reason of Peary's mistake. The course of the " channel " between J. P. Koch Fjord and Bronland Fjord is occupied by a long low valley, the flow of which is about 200 metres above sea level. Wandel valley, as it is named, separates Peary Land from the rest of Greenland. Peary Land is thus virtually an island, and probably during the period of greatest glacial subsidence in the past was entirely separate. It consists of a northern mountain mass of two parallel chains each rising to above 2000 metres and a southern plateau nowhere over 1000 metres. This plateau is low in the east and higher in the west. Local glaciers fill many of the valleys. The expedition also did important surveys in Wulff Land at the head of Sherard Osborn Fjord and in Washington Land, east of Kennedy channel.

EARTHQUAKE IN THE BAY OF CHIJIWA.—The Journal of the Meteorological Society of Japan for January contains an article by Mr. Saemontaro Nakamura on the earthquake which occurred near Nagasaki on December 8, 1922, when 27 persons were killed, 11 were injured, and 182 houses were destroyed. Microseismic observations at several stations, the directions and durations of the earth-sound in the epicentral region, and the direction and intensity of the shocks, indicate an epicentre in the Bay of Chijiwa. It had the typical tectonic characteristics with regard to the time of distribution of after-shocks, and the distribution of the direction of the first movement at stations about the epicentre. The axis of the dislocation deduced by the first movement coincides with a geographical, or geological feature of the locality. It caused no changes on Mt. Unzen, an active volcano quite near the epicentre of the earthquake. It may be supposed that this earthquake has no direct relation with the volcanic eruption of Mt. Unzen. The locality affected is situated about 500 miles to the west-south-west of the recent intense earthquake which involved Tokyo, Yokohama and the surrounding country.

WEATHER IN CANADA.—The meteorological service of the Dominion of Canada publishes regularly a monthly Weather Map, and the map for July last has recently reached us. Observations of air temperature and rainfall are shown for the several meteorological stations comprised in the chart. The differences of temperature from the normal are indicated by lines, much as we show isotherms. Rainfall amounts are shown by a varying degree of shading. July temperatures were higher than normal over most of the interior of British Columbia, in Alberta, Saskatchewan, Manitoba, and Kenora, Rainy River and Thunder Bay regions of Ontario. From the eastern end of Lake Superior to the Atlantic Ocean they were below normal. The greatest excess of temperature, about 8°, occurred in Manitoba, and the greatest defect, about 6°, in northern New Brunswick. Precipitation over the greater part of the wheat region of the Western Provinces ranged from three to seven inches. Coupled with the meteorological notes, the conditions of crops and fruit are shown for the different parts of the Dominion.

SALT-MARSH MOSQUITOES.—The valuable work of Mr. J. F. Marshall and his associates on the Hayling Mosquito Control has already been commented upon in these columns (NATURE, August 19, 1922, p. 261) in reviewing the first report of that body. Since then steady progress has been made, as instanced in the second report (issued in May last) and in a recent article and letter in the *Field*. For any success in mosquito control work it is essential to arouse public interest and co-operation, and Mr. Marshall has succeeded in doing this at Hayling Island. Further, it is satisfactory to learn that the example of Hayling has already been copied by Gosport, where a similar local " control " has been organised under the

energetic direction of Surgeon-Commander D. H. C. Given. In the words of Mr. Marshall, "Both in Hayling and Gosport the mosquito nuisance has already decreased by an almost unbelievable extent." This satisfactory result is largely due to the preliminary biological investigations. These showed, first, that practically the whole of the nuisance was due to one particular species, *Ochlerotatus detritus*. Not only was it found that this species far outnumbered all the others put together (in the proportion, it is said, of not less than 1000 to 1), but also it was found that the domestic *Culex pipiens*, present in fair numbers, was not addicted to sucking human blood. In the second place, the very important discovery was made that *O. detritus* will only breed in more or less salt water which is allowed to stagnate. The control of this species is therefore largely a matter of ensuring that no salt water is allowed to become cut off from tidal action, and by united effort this can be done in any of the coastal towns where this particular species is the chief offender against the comfort of the inhabitants. Such work must, however, cover a considerable area, for *O. detritus* has been found to spread at least four miles from its breeding-grounds. The experiences at Hayling should prove valuable in any attempts which are made in the control of our second salt-marsh species, *Ochlerotatus caspius*, which is now known to be the chief cause of the mosquito nuisance in the London area, as well as at some East Coast resorts. In this case, however, the problem is complicated by two difficulties: in the first place, *O. caspius* does not breed *exclusively* in salt water, and, secondly, its range of flight appears to be much greater than that of *O. detritus*. It can scarcely be doubted, however, that a much closer study of the distribution and biology of *O. caspius* would reveal facts of which practical use could be made in reducing its numbers. The prime importance of such biological work has been well illustrated at Hayling.

CAINOZOIC AND RECENT AUSTRAL RHYNCHONELLIDS.—In NATURE, vol. 110, p. 262, 1922, the fate that has overtaken the genera Terebratula and Rhynchonella, mostly under the penetrating eye of Mr. S. S. Buckman, was mournfully recorded. Mr. F. Chapman (Proc. Roy. Soc. Victoria, vol. 35, p. 175, 1923) now finds that Hutton's *Rhynchonella squamosa* must become the genotype of a new genus (here called by a misprint "sp. nov."), which he names Tegulorhynchia. A critical description, with figures and a bibliography, is given of the Cainozoic and recent rhynchonellids of the austral region.

HARD X-RAY TUBES.—In the issue of *Die Wissenschaften* for September 7, Prof. Knipping, of Heidelberg, gives a summary of his work on the cause of the inability to transmit electric current which is found in X-ray tubes after they have been in use for some time, even when the pressure of the residual gas in them is raised to 0·01 mm. of mercury by the regenerative arrangement with which they are generally provided. He finds that the effect is due to the absence of positive nuclei of hydrogen atoms which are necessary to render any gas at low pressure conducting. In their absence a gas at the above pressure behaves towards the passage of electricity like a perfect vacuum, and the author speaks of such a gas as a pseudo high vacuum. In normal circumstances the hydrogen nuclei are provided by the moisture which is condensed on the walls of vacuum tubes, and continued use of the tubes exhausts this supply. Prof. Knipping is continuing his investigation, and points out that the present theory of the emission of electrons from heated bodies requires modification to include the effect of the surrounding medium.

COLLOIDAL PROPERTIES OF RICE STARCH.—It is well known that the granules of starches vary not only in their appearance according to their origin but also in their properties; thus sago, tapioca, and cassava starches yield more glutinous sols than others. This difference is well marked between the common and glutinous rice starches, and Messrs. T. Tadokoro and S. Sato have made this the subject of an interesting paper in the Journal of the College of Agriculture, Hokkaido Imperial University (1923, vol. 13, p. 1-65). These authors show that there is a difference in the behaviour of the two kinds of granules towards iodine, and both in suspension and in dilution the affinity of glutinous starch for iodine was less than that of ordinary starch. Coagulation of the solutions by the addition of alcoholic hydrochloric acid or by solutions of metallic salts was obtained more readily with ordinary starch. The colloidal properties as shown by the hydrating power, water retention, viscosity and protective action (gold value) of the strong solutions was greater in the case of glutinous starch, thus indicating the greater dispersion of this substance in solution. In the formation of a jelly by the addition of tannin solution, a greater quantity of the reagent was required for the glutinous starch, and the ultramicroscopic appearance of the gel resembled a network instead of a foam as shown by the gel of ordinary starch. Further differences were shown by the two varieties of starch with regard to the decomposition of the blue iodine compounds by X-rays and various reagents, and the adsorbent power of charcoals derived from the starches by ignition. In spite of the many differences in colloidal behaviour of these two starches, there was no noticeable variation in their ordinary chemical properties. The observed differences are attributed to a different degree of polymerisation between the starches.

LIQUID FUELS IN AUSTRALIA.—The Australian Commonwealth Institute of Science and Industry has issued a bulletin (No. 24) compiled by R. E. Thwaites on "The Production of Liquid Fuels from Oil Shale, and Coal in Australia." The main part of the bulletin is occupied with a survey of mineral oil supply viewed as a world problem. It gives an interesting and comprehensive review, both technical and economic, together with speculations as to the future sources of liquid fuel. The problem is then analysed as it bears upon Australia itself. There the conditions seem to resemble those of Western Europe. Proved deposits of mineral oil are scanty or non-existent. Home produced liquid fuel will have to be derived from oil shales, lignites, and bituminous coal, of which considerable deposits are now exploited or known. The oil shales though rich are limited in quantity and an existing industry engaged in their distillation is at a standstill, rendered unremunerative for the moment by high working costs. The proved deposits of such shales would not, however, furnish Australian requirements at present rates of consumption for more than ten years. The supply in the future will have to be based on coal and brown coal both occurring abundantly. The existing towns' gas industry, carbonising coal at high temperatures, already makes a useful contribution of liquid fuel. The author looks for greater production in the future from this source and from developments of carbonisation at low temperatures. The technical and economic problems involved are recognised and a plea is advanced for the institution of a fuel research laboratory to explore the subject with special reference to Australian conditions.

Royal Photographic Society's Exhibition.

THE sixty-eighth annual exhibition of the Royal Photographic Society was opened on Saturday, September 15, at the Society's house, 35 Russell Square. It will remain open until October 27, and admission is free.

The scientific and technical section is, this year, divided into nine subsections, and it would have been a great improvement if this division had been maintained in the exhibition itself, for those interested in these matters prefer a clear classification to symmetrical hanging. There is a total absence of astronomical exhibits, and the exhibition is the poorer for it. Still, the space available, which is more than heretofore, is well filled with good and interesting work. Any one who delights in animals of all sizes, birds, insects, etc., will find a selection of work that probably has never been excelled. Of special interest is Mr. Oliver G. Pike's demonstration of the use of kinematography in his enlargement from a film showing in eight stages at half-second intervals a cuckoo approaching a meadow pipit's nest, taking out one of the eggs, laying its own egg, and flying off with the stolen egg, which it then eats.

The American Raylo Corporation illustrate Mr. H. C. J. Deek's three-colour process, which does for colour prints on paper what the introduction of gelatin plates did for ordinary negative making. It simplifies the operations and eliminates many of the difficulties. The three negatives are taken consecutively, side by side, on a small plate, but the changing of the screens and the shifting of the plate are done mechanically, and the total time occupied may be as short as one quarter of a second. Each record on the triple negative measures 1 in. × 1½ in. Development is done in a metal box, no dark room being necessary. The final prints are 5 in. × 7 in. The negative is enlarged upon a sheet which has upon it side by side the necessary red, yellow, and blue pigmented and sensitised gelatin films, each on a thin sheet of celluloid. It is developed in warm water, and the superposition of the three is done by means of a special adjusting frame, so that the accurate register is very easily secured.

The radiographic prints exhibited are specially noteworthy. The human hand taken with an exposure of one-twentieth of a second by Mr. A. A. Campbell Swinton is compared with the radiograph made by Mr. Campbell Swinton in 1896 (the first made in England) which required 20 minutes' exposure. Dr. Robert Knox shows, among others, radiographic records of the movement of the left border of the heart, in a normal condition and in a case of heart block. These are taken with a slit diaphragm and a moving film.

There is a considerable section of photomicrographs which includes examples of almost every possible kind. Mr. F. Martin-Duncan has prepared specimens of the hairs of the primates by a special mounting process and illuminated them in a special manner, so as to show the extremely delicate cuticular scales on the outer surface. These are of great importance as a certain means of identification and classification. Mr. J. H. Pledge shows a series which demonstrates the variation of stem structure in successive years of a twig of mistletoe.

Specimens of the use of the Low-Hilger Audiometer are shown by Prof. Low and also by Messrs. Hilger. These include the Melba trill, the Melba exercise for the cure of corns on the vocal chords, and sound wave records of several musical instruments.

The Royal Air Force has a series of photographs taken from aeroplanes, which demonstrate to what a wonderful degree of perfection this method of work has been developed. Two aeroplanes in collision at Northolt last June were photographed at the critical moment by Mr. G. V. Grundy. Mr. H. Roussilhe shows drawings of the apparatus used for the correction of aerial photographs and the production from them of plan maps, with specimens of the steps in the process.

Among the stereoscopic prints, lantern slides, and colour transparencies will be found many of excellent quality. The "Cine-Kodak" and the "Kodascope," which reduce the cost of taking "moving pictures" to one-fifth that of the standard apparatus, will be demonstrated at 11.30 A.M. and 3 P.M. each day. These machines have already been referred to in these pages (NATURE, September 1, p. 333).

The European Drought of 1921.

A LENGTHY discussion of diverse aspects of the great drought is afforded by Prof. Filippo Eredia in a paper entitled "La Siccità del 1921," published on the authority of the Ministry of Public Works, Rome, in 1922. Although the dry weather of that year appears to have affected in varying degrees practically the whole of Europe, and in conjunction with the political situation led to the terrible famine in Russia, the region dealt with in this communication is limited to Italy, Switzerland, France, and Britain, and for the last-named country the author avails himself of the material supplied by Messrs. Brooks and Glasspoole (Quart. Journ. Roy. Meteor. Soc., vol. 48, 1922).

In Ireland, and in Scotland except on the east coast, the rainfall of 1921 did not, as a rule, fall below 80 per cent. of the normal, and as over much of these two countries the normal amount is heavy, the deficiency of 20 per cent. did not mean any real condition of drought except, perhaps, for quite brief periods now and then during the course of the year. But in eastern and southern England, and the major portion of France, the total fall in 1921 only amounted to from 60 to 50 per cent. of a much lower average, so that the economic consequences of a deficiency equal to half the average were very serious. Locally in the extreme S.E. of England the rainfall of 1921 was less than 50 per cent. of the average, while in many places in southern and eastern France, Switzerland, and northern Italy it barely exceeded 40 per cent., *i.e.* a deficiency of nearly 60 per cent. In London the rainfall of the year was the lowest for at least 150 years, and was actually less than the evaporation—a very rare occurrence in the damp, cool climate of England. But whereas in England, France, and Switzerland the most intense phase of the drought coincided with the midsummer heat of June and July, in Italy the dearth of rain did not become acute before September, after which in northern or continental Italy there was practically no rain till the beginning of 1922, the month of October, normally the wettest in the year, being absolutely rainless at Milan and other places—a unique occurrence for that month.

In central and southern Italy, on the contrary, the deficiency of rainfall in the last three months of 1921 was less marked than in the north, while the normal summer Mediterranean drought of peninsular and

insular Italy was actually less rigorous than usual. In continental Italy the snowfall both in the mountains and plains during the early months of 1921 was very light, and this coupled with the almost entire absence of rain in the autumn caused the Alpine streams at the end of the year to fall lower than had ever been remembered. Perhaps the most interesting feature in the geographical distribution of the drought, as concerns the four countries named, is the general intensification from England in the N.W. to Italy in the S.E.—that is from a more oceanic to a more continental regimen of climate. (See article in Nature on "Climatic Continentality and Oceanity," April 21, p. 549.) It is known that both excesses and deficiencies of rainfall with respect to the average are normally more marked in continental than in maritime regions, and the reason is not difficult to understand when one reflects that rainfall is but a by-product of the circulation of the atmosphere and the changes of temperature, in the several strata, associated therewith. Hence, one would expect vicissitudes of rainfall to bear some relation to continentality, because all variations of temperature, seasonal, diurnal, or irregular, tend to be accentuated on land and damped out on sea.

In France and England the drought, which was essentially a summer one, commencing about February and terminating about November, was connected with a marked excess of barometric pressure over central Europe. There seems to be no doubt that the normal Mediterranean high pressure was in the summer of 1921 displaced northward, permitting secondary depressions to develop now and then over the Mediterranean Sea, with alleviation of the ordinary summer drought in that region as stated above. In England during the summer we were commonly located in the northern portion of the French anticyclone, with the usual westerly winds but without the usual moisture. More usually we lie farther towards the polar edge of the south-westerly winds, which are then associated with the convergent air-streams of barometric depressions; but evidence has been adduced ("British Rainfall, 1921") that in 1921 there was a greater preponderance of divergent air-currents.

It is important that students endeavouring to understand something of the origin of rainfall in England should co-ordinate the more distant point of view of the physical geographer who associates our rainfall with the abundant moisture supplied to the south-westerly winds by the warm Atlantic Drift, with the more immediate point of view of the meteorologist who relates it to the incidence of barometric depressions, that is, of convergent and ascending air. Students, too, accustomed to think of the proverbial dryness of east winds in Great Britain, are often greatly puzzled by the persistent rain we not infrequently experience with wind from that quarter. There is no discrepancy, however; for in many cases of rain with east wind on the northern side of a depression, the moisture is supplied by an Atlantic current above the drier easterly current through which the rain is falling.

L. C. W. Bonacina.

University and Educational Intelligence.

London.—An attractive series of free public lectures during the Michaelmas term has been arranged at King's College. Prof. A. Dendy is giving nine lectures on Wednesdays, commencing October 17, on the biological foundations of society; Mr. R. Aitken, five lectures on the geography of Spain and typical Spanish institutions, on Thursdays, commencing November 1; Prof. H. Wildon Carr, four lectures on the Hegelian philosophy and the economics of Karl Marx, on Tuesdays, commencing October 9; and Miss Hilda D. Oakeley, three lectures on the roots of early Greek philosophy, on Tuesdays, commencing November 27. In addition, Prof. R. J. S. McDowall, of Edinburgh, is giving an inaugural lecture in the Department of Physiology on the position of physiology in science and medicine on October 4, and Prof. W. T. Gordon is giving the Swiney lectures (12) on geology on Mondays, Wednesdays, and Fridays, commencing November 19, taking as his subject "Gem Minerals and their Uses in Art and Industry." The lecture hour in every case is 5.30 p.m.

At University College, the list of public lectures includes the following: introductory lecture by Sir Flinders Petrie on religious life in Egypt, on October 4 at 2.30 p.m.; three lectures on the new Babylonian creation and flood stories, by Dr. T. G. Pinches, beginning on October 4; an introductory lecture by Prof. C. Spearman on psychology as transfigured behaviourism; and a course of lectures by Prof. J. A. Fleming on ionic and thermionic valves, beginning on October 24. Single lectures are to be given by Miss Margaret Murray, on primitive religion, on October 5; by Prof. G. Dawes Hicks, on the philosophy of Bernard Bosanquet, on October 8; by Mr. Morris Ginsberg, on the sociological work of the late Dr. W. H. R. Rivers, by Mr. A. H. Barker, on the heating equipment of a small house, and by Miss I. C. Ward, on the application of phonetics to the curing of speech defects, at various times on October 10; and an inaugural lecture by Prof. A. V. Hill, on the present tendencies and future compass of physiological science, on October 16. Particulars of the lectures and courses should be obtained from the Secretary of University College.

A course of six lectures on the bearing of psycho-analysis upon sociological problems has been arranged by the Sociological Society, Leplay House, 65 Belgrave Road, Victoria, S.W.1. The lectures are to be given on Tuesdays, and commence on October 9 with an introductory lecture by Dr. Ernest Jones. Succeeding lectures will deal with man as an individual, the family, politics, education, and vocation. Half-price tickets are available for a limited number of students.

A series of "Celebrations," arranged by Dr. F. H. Hayward, Inspector of Schools, of 87 Benthall Road, London, N.16, will be held during the winter on certain Saturday evenings (6 o'clock) at the Birkbeck Theatre, Birkbeck College, Fetter Lane, E.C. Four of these in particular may be of interest to readers of Nature, namely: Two homage celebrations, "The Geologist," December 1, and "The Scientist" (in general), March 1, 1924, and two memorial celebrations, "Leonardo da Vinci," January 12, 1924, and "Goethe," February 9, 1924. All these four have a predominant scientific interest. Though we understand that Dr. Hayward has found it difficult to discover music and poetry that can be effectively employed in the glorification of science and its devotees, he has discovered some, and he thinks that the main purpose of the celebrations will be achieved, namely, the creation of emotional associations in connexion with the history and the methods of science. Recent studies in psychology and sociology have pointed to the conclusion that knowledge and reason are more closely related to instinct and emotion than was formerly believed. Without an emotional basis, they cannot flourish or even receive adequate recognition among the mass of mankind. Hence the importance of Dr. Hayward's attempt to employ "mass" methods and other devices.

Suggestions and criticisms are invited. Mozart's "Magic Flute" will supply some items of music, especially on March 1. Admission will be free, without ticket.

SECONDARY education in the United States in 1921 and 1922 is reviewed in Bulletin, 1923, No. 12, of the Bureau of Education, Washington. The outstanding achievement within the past few years has been an extension downwards of the secondary school system in many parts of the United States, especially in cities. Typically, the extension has taken the form of substituting for the normal sequence of 4 years of high school work following 8 years (ages 6 to 14) of elementary schooling, a system sometimes described as the 6-3-3, meaning 6 years (ages 6 to 12) of elementary schooling followed by 6 years of secondary school work divided into two administrative units of 3 years each, namely, the junior high school and the senior high school units. Essentially the change implies that the passage from the elementary to the secondary type of curriculum should synchronise with the commencement of the physical changes of adolescence. It is generally agreed in America that at this stage the pupil needs in his studies change, variety, and human interest rather than completeness and logical arrangement, and that consequently in place of the traditional seventh and eighth grade courses there should be a general survey of the chief departments of knowledge: "English literature, general social science, general mathematics, general science, foreign languages for those who desire them, music, art, physical education, and the practical arts." This holds good both for those who are to leave school at 15 and for those who are to pass on to the senior high school.

A STATISTICAL survey of education in the United States is given in Bulletin No. 16 of 1923 of the Federal Bureau. It shows the following total enrolments in 1919-20 (in thousands): kindergarten 511, elementary 20,383, secondary 2430, university, college, and professional school 462, teachers' college and normal school 163; grand total 23,950, being 22·7 per cent. of the total population. Included in the above are the following enrolments in private, that is non-state, institutions: kindergarten 30, elementary 1486, secondary 229, university etc. 281, teacher-training 14. The estimated cost of all this education, except private elementary and private secondary, is 1301 million dollars, or, in dollars per head: elementary 39, secondary 127, university, college, and professional 460, teachers' college 131, other normal schools 189. The figures are exclusive of city evening, private commercial, nurse-training, and Indian and Alaskan schools. Enrolments in these amounted to 587, 336, 55, and 32 thousands respectively. Gifts and bequests to education in 1920 reached the unprecedented total of 67 million dollars, the highest previous record being 37 million in 1916. The extent to which women teachers have taken the place of men during the past 40 years in elementary and secondary schools is strikingly shown in a table in another Bulletin, No. 29 of 1922, giving the percentage of men teachers in 1880 and at the end of each subsequent quinquennium up to 1920: 43, 37, 35, 33, 30, 24, 21, 20, 14. The average annual salaries in dollars of all teachers, men and women, in the same years are given as 195, 224, 252, 286, 325, 386, 485, 543, 871, but the last figure includes supervisors and non-teaching principals. During the past 50 years the ratio of pupils in secondary schools, compared with the total enrolment in elementary and secondary schools combined, increased from 1·2 to 10·2 per cent.

Societies and Academies.

LONDON.

Institute of Metals (Manchester Meeting), September 10.—Sir Henry **Fowler**: The use of non-ferrous metals in engineering (Autumn Lecture). Of the non-ferrous metals used by engineers, the one which has been in longest use is copper, and it is at present the one most closely associated with engineering work. The uses to which its comparatively simple alloys with tin and zinc can be put are endless. The next in importance is tin, which, alloyed with copper, lead, and antimony, gives us those white metals which are used to make bearings in machines. Aluminium is still most generally used in connexion with aeronautics.

September 11.—E. A. **Bolton**: The cause of red stains on sheet brass. The stains occur through reactions of copper oxides in the scale formed during annealing and in the pickling medium. Cupric oxide, contrary to the usual opinion, is as harmful as cuprous oxide. The presence of these oxides may be due to careless washing after pickling, resulting in the presence of acid and salts during annealing, the presence of iron in the brass or upon its surface, the use of impure rolling oils, etc. The main cause of the oxidation of the copper is the use of old-fashioned annealing furnaces in which the flames impinge directly upon the brass. Possible remedies for the red-stain trouble are suggested.—H. W. **Brownsdon**: Brinel hardness numbers. Brinel numbers for non-ferrous metals should be expressed in figures that are comparable. This could be done if balls and loads are used for which the ratio L/D^2 (the load in kilograms divided by the square of the ball diameter in millimetres) is constant. Some one ratio for L/D^2 should always be used for one class of alloys; for the copper alloys with Brinell hardness numbers from about 40 to 200, the choice should rest between the ratio 5 as standardised in the United States or the ratio 10 which is favoured in some quarters in Great Britain.—A. H. **Mundey** and John **Cartland**: Stereotyping. Stereotyping is generally regarded by printers as almost a trade secret. The process was invented by a practical metallurgist, William Ged, an Edinburgh goldsmith, in 1750. Stereotyping was traced from the plaster-of-Paris process to the use of papier-maché flong, and from the simple stereo plates for flat-bed machines to the elaborate requirements of the modern newspaper. A high degree of accuracy is demanded in the mechanical and metallurgical details in order to produce the good results which are a commonplace to everyone.—J. D. **Hannah** and E. L. **Rhead**: Crystallisation effect on galvanised iron sheets. Manufacturers of galvanised iron and steel goods always seek to produce a zinc-covered surface having large characteristic spangles. Small spangles or lack of spangles is disliked. The metal—iron or steel—has practically no influence on the result if the temperatures are satisfactorily maintained. Pure zinc does not yield large spangles, and too high a temperature interferes by producing large quantities of a zinc-iron compound which crystallises in needles on the metal. The presence of tin or aluminium does not produce the desired result, but lead is effective. The separation of the impure zinc into conjugate solutions, lead-rich and zinc-rich, at the dipping temperature, and the method of subsequent crystallisation, may be the causes of these effects.—R. C. **Reader**: Effects of rate of cooling on the density and composition of metals and alloys. The densities of pure metals, and of alloys which solidify at a constant temperature, are not affected by the rate at which they solidify.

With alloys which solidify over a range of temperature, the slower the rate of solidification the lower is the density, and when they are prepared in cylindrical chill moulds, they are less dense in the centre than at the outside. When prepared in chill they are richer on the outside in the component of the lower melting point.—A. H. **Mundey** and C. C. **Bissett**: The effect of small quantities of nickel upon high-grade bearing metal. Nickel is now added to the well-known bearing metal consisting of tin 93 per cent., antimony 3·5 per cent., copper 3·5 per cent. Tensile, compression, and hardness tests gave no indication of improvement. The comparison of hardness at varying increased temperatures exhibited no improvement. In the case of the alloy with no nickel, the hard copper-tin constituent is very marked in its characteristic crystalline formation as seen under the microscope. The presence of nickel even in small quantities results in a great diminution of this crystalline structure.—Hikozo **Endo**: The measurement of the change of volume in metals during solidification. In the casting process it is very important to know to what extent a change of volume occurs during solidification. In 1888, Vincentini and Omodei calculated the change of volume of some fusible metals during solidification from the change of density at the melting point. E. Wiedemann, Paul Pascal, and Louis Hackspill also used this method. M. Toepler studied the change of volume by means of a dilatometer; he suggested a relation of the change of volume of a metal at melting point to its atomic weight. K. Bornemann and F. Sauerwald measured the density of metals at various high temperatures, using the principle of Archimedes, by means of a mixture of sodium and potassium chlorides as liquid. The method of investigation now used for metals having melting points up to 1100° C., which was suggested by Prof. K. Honda, consists in the measurement of the change of buoyancy of a metal suspended in an inactive liquid during its solidification or melting by means of a thermobalance.

September 12.—Marie L. V. **Gayler**: The constitution and age-hardening of the quaternary alloys of aluminium, copper, magnesium, and magnesium silicide. Alloys containing up to 6 per cent. copper, 4 per cent. magnesium, and 4 per cent. magnesium silicide were used. When copper, magnesium, and magnesium silicide are present in aluminium, any two of these components have a marked effect on the solubility of the third and ultimately $CuAl_2$ and Mg_2Si are both thrown out of solution. If copper and magnesium are present in a ratio greater than 12 to 5 approximately, then the alloys when quenched from high temperatures age-harden at room temperature, owing to the difference in the solubility of Mg_2Si at the quenching and ageing temperature. Age-hardening of alloys of the "Duralumin" type is due primarily to Mg_2Si, and the addition of magnesium and copper is important since both reduce the solubility of Mg_2Si at high and low temperatures and consequently reduce the maximum age-hardness due to Mg_2Si.—Ulick R. **Evans**: The electro-chemical character of corrosion. There are two main types of corrosion: (1) that accompanied by evolution of hydrogen is characteristic of reactive metals placed in acid solutions, but the velocity varies greatly with the degree of purity of the metal; (2) slower corrosion, determined by the diffusion of oxygen to the metal, and comparatively independent of the purity. When a metal is immersed in a solution of potassium chloride, alkali is produced at the cathodic portions, the chloride of the metal at the anodic portions, and the hydroxide is precipitated where these meet. The electric current produced accounts for the greater part of the corrosion actually observed. Generally the cathodic areas are those to which air has free access, while the anodic areas are those protected from aeration. Corrosion usually proceeds most rapidly at the comparatively unaerated places—hence the intense corrosion observed in "pits" and over areas covered up by porous corrosion-products.—Douglas H. **Ingall**: Experiments with some copper wire; cohesion a function of both temperature and cold work. Five samples of copper wire were used: soft annealed and four degrees of cold work given by 25, 40, 50, and 75 per cent. reduction of area by drawing. The cohesion at high temperatures was determined by placing given loads on the wire at atmospheric temperature, heating the wire and determining the temperature at which it broke. All the samples gave similar graphs in which with rise of temperature the cohesion decreased along a straight line to a constant critical temperature of 350° C., beyond which the cohesion was represented by a sharply descending curve. The equations to the straight lines $C = a - bT$ and to the curves $TC^n = k$ (where C = cohesion and T = temperature) showed that the percentage increase of the constant b and the percentage decrease of the constant n were represented by the corresponding percentage reductions for any given cold worked wire, with the exception of 75 per cent. reduced wire. At the critical inflection temperature the material was comparatively extremely fragile.—D. **Hanson**, C. B. **Marryat**, and Grace W. **Ford**: Investigation of the effects of impurities on copper. Pt. I.—The effect of oxygen on copper. The effect of oxygen, up to a concentration of 0·36 per cent., on *pure* copper, was investigated. The mechanical properties are not much affected by small quantities of oxygen, and copper containing as much as 0·1 per cent. differs very slightly from pure copper. The electrical conductivity does not fall rapidly, and values exceeding 100 per cent. of the International Standard are obtained in all annealed materials containing less than 0·1 per cent. of oxygen. This is due to the low solubility of the oxide in solid copper. The oxygen-bearing metals can be considered as a heterogeneous mixture of pure copper and finely divided particles of cuprous oxide. There is a soft ductile copper matrix, in which harder particles of cuprous oxide are distributed so as to form a mechanical mixture.—Hugh **O'Neill**: Hardness tests on crystals of aluminium. Brinell tests showed that at low loads the different crystallographic planes resist penetration to different degrees, and give indentations of different shapes. In the Brinell sense the (110) face is the "hardest" and the cube (001) face appears to be the "softest." But the load required to immerse the ball is apparently the same in all cases. Crystal boundaries are without any appreciable effect in increasing the resistance of aluminium to penetration.—H. I. **Coe**: The behaviour of metals under compressive stresses. Compression tests carried out on small cylinders of metals show that with successive increments of loads plastic flow occurs, after the elastic limit has been exceeded, at an increasing rate. At a certain load the rate of flow changes abruptly, metals such as tin and lead becoming perfectly plastic, harder metals becoming more plastic than under preceding loads and immediately succeeding loads. The term "critical plasticity" is used to indicate the change in the rate of plastic deformation which most metals exhibit at a particular load. Annealed metals flow at a comparatively low load and the rate of flow increases up to the load corresponding to critical plasticity; when worked, they are more resistant to compressive stresses until they approach the load corresponding to a critical plasticity, when they suddenly collapse and a marked temporary flow occurs.—Albert M.

Portevin and **Pierre Chevenard**: A dilatometric study of the transformations and thermal treatment of light alloys of aluminium. Dilatometric methods, using the recording differential dilatometer, permit of the study of the transformations and the mechanism of heat-treatment of the light alloys of aluminium-magnesium-silicon, and in general, of alloys containing two-phase, univariant transformations. The study of the constant temperature transformations by the differential dilatometer, using a high sensitivity apparatus, leads to general expressions representing the phenomena as functions of time and temperature. Quenching and tempering in these alloys can be interpreted by the known variations in the solubility of Mg_2Si in the solid state, without assuming any further transformations.—P. **Soldau**: Equilibrium in the system gold-zinc (based on investigations of electrical conductivity at high temperatures). The alloys of gold and zinc belong to the type of AR-brasses, where A is a metal belonging to the first and R to the second group of the periodic system. These alloys are of considerable practical importance, as in their chemical nature they are very close to the ordinary brasses. For the determination of electrical conductivity at high temperatures, a special apparatus was constructed which was checked by determining the transformation temperatures in iron and steel and comparing the results with those obtained by other methods.

PARIS.

Academy of Sciences, September 3.—M. A. d'Arsonval in the chair.—Alfred **Errera**: A theorem of linkages.—Alexandre **Rajchman**: The Riemannian theory of trigonometrical series.—M. **Puthomme**: Contribution to the study of the secondary X-rays. Two metallic wires, in the form of a cross, give a single sharp radiographic image, but if a metallic screen such as a sheet of lead, be placed between the X-ray bulb and the wires, then three images are observed, one on each side of the initial image. The two additional images are due to secondary rays starting from the edges of the lead screen. The fact that a needle imbedded in the body may sometimes give a faint extended image rendering it difficult to locate is probably due to the same phenomenon.—E. F. **Terroine**, P. **Fleuret**, and Th. **Stricker**: The rôle of the deficient proteids in supplying the minimum nitrogen requirement. Experiments on the nitrogen assimilated by growing pigs from ammonium citrate and from gelatin. The amount assimilated varies greatly with the individual animal. Gelatin proved to be superior to ammonium citrate as a source of nitrogen.—Mme. **Randoin**: Study of the vitamins in molluscs. The presence of the antiscorbutic factor in the oyster. From experiments on guinea pigs it is concluded that the addition of oysters in suitable quantity to a diet not containing vitamin-C is sufficient to prevent symptoms of scurvy.—M. **Athanassopoulos**: The tunny fish of Greece.

Diary of Societies.

MONDAY, OCTOBER 1.

SOCIETY OF ENGINEERS (at Geological Society), at 5.30.—A. Ferguson, Improved Method for Mass Production of Tank Glass Bottles, Jars, etc.

WEDNESDAY, OCTOBER 3.

SOCIETY OF PUBLIC ANALYSTS (at Chemical Society), at 8.—J. H. Coste, E. R. Andrews, and W. E. F. Powney: The Sampling of Coal; the General Problem and some Experiments.—H. G. Stocks: A New Test for distinguishing Castor Oil.—A. E. Etheridge: The Volumetric Estimation of Vanadium in Steel.—C. L. Hinton and T. Macara: The Iodimetric Determination of Sugars.

THURSDAY, OCTOBER 4.

CHILD-STUDY SOCIETY (at the Royal Sanitary Institute), at 6.—Discussion opened by Miss Norah March: The Report of the Commission in relation to the Teaching of Biology in Schools.

CHEMICAL SOCIETY, at 8.—E. B. R. Prideaux and A. T. Ward: A Revision of the Dissociation Constants of Weak Inorganic Acids. Part I. Boric Acid. Part II. Phosphoric Acid.—C. N. Hinshelwood and C. R. Prichard: Two Heterogeneous Gas Reactions.—C. N. Hinshelwood and C. R. Prichard: A Homogeneous Gas Reaction. The Thermal Decomposition of Chlorine Monoxide. Part I.—R. G. W. Norrish and E. K. Rideal: The Direct Union of Oxygen and Sulphur.—W. R. Ormandy and E. C. Craven: Note on Aqueous Formaldehyde Solution.—H. Hawley and H. J. S. Sand: The Interaction of Potassium Tetroxide with Ice and with Dilute Sulphuric Acid.

PUBLIC LECTURES.

THURSDAY, OCTOBER 4.

UNIVERSITY COLLEGE, at 2.30.—Sir Flinders Petrie: Religious Life in Egypt (Introductory Lecture).

LONDON SCHOOL OF ECONOMICS, at 5.—Sir Arthur Newsholme: Measurement of Progress in Public Health (William Farr Lecture).

UNIVERSITY COLLEGE, at 5.15.—Dr. T. G. Pinches: The New Babylonian Creation and Flood Stories. (Succeeding Lectures on October 11 and 18.

KING'S COLLEGE, at 5.30.—Prof. R. J. S. McDowall: The Position of Physiology in Science and Medicine.

FRIDAY, OCTOBER 5.

UNIVERSITY COLLEGE, at 5.—Miss Margaret A. Murray: Primitive Religion.

The Imperial Conference and Natural Resources.

AMONG the problems being discussed at the Imperial Conference, now being held in London, one of the most important is the development of the natural resources of the British Empire, and this is a question which can no longer be approached on old-fashioned empirical lines. On the contrary, a successful solution can be expected only if the whole matter is put on a rigidly scientific basis.

The first need is for a scientific survey of each area of the Empire as a possible home of man. The result of such a survey would be a store of definite knowledge as to (1) the various raw materials (food and other) to be expected from each area, and (2) the extent to which any area at present contributes its proper share of such raw materials.

Two facts must, however, be faced before entering on any such survey for any part of the Empire. One is that the Empire is, politically and economically, oceanic. We depend on the ocean not only for strategic security, but also for economic and commercial prosperity; and our consciousness of this has tended or tempted towards excessive dependence, in the form of neglect of the tiny, but vital, home supplies, until we no longer attempt to grow bread enough for our needs during even a quarter of the year. Indeed, Mr. Churchill's famous motor park is still a wilderness of hulks cumbering some of the best wheat land in England; and across the Middlesex border from Slough a housing authority thought that the best "brick earth" in Middlesex was a good foundation for brick cottages. We may agree entirely that "working men had as much right as any one else to the best land in the parish," and yet question the suitability of "brick earth" for any house-sites and resent its being alienated from its proper work of providing food by intensive culture.

Space forbids detailed treatment of the homeland, but the fundamental factors must be kept in mind. In the first place, we ought to add 8,000,000 acres to our arable area, and put 250,000 men on them; then, in any emergency, we could guarantee four-fifths of the adequate minimum of wholesome and nourishing food for all our people. Then literally some millions of our people never taste a drop of fresh English milk; and the way to increase and cheapen the supply is to increase our arable area. Denmark is so small and so highly specialised that it scarcely gives a fair comparison. But in 1913 even Germany produced 485 lb. of "bread" per head of population (against our 90 lb.), and so had only 25 per cent. of her farm area under grass (against our 60 per cent.), and was able to rear one head of cattle to the acre, while we reared only one to three acres.

Lastly, our method of raising meat is appallingly

wasteful. It takes 48 lb. of cereals fit for human use to raise one pound of beef; even the pig, by far the most economical converter, consumes 3,000,000 tons of "human" food to produce 250,000 tons of pork, ham, and bacon. The saving of time and money and ships, if we imported the meat instead of the food for cattle, would almost pay our whole unemployment dole; and even the bacon, equal in quality to that for which we paid Denmark about 30,000,000*l.* last year, could be imported from our own tropical dominions, for tropical bacon is as "firm" as English bacon, if the pigs are given coconut in their food.

The British Empire, unlike other big empires, is an epitome of the world, so that we have naturally a climatic base for classifying natural regions; and we can distinguish half-a-dozen broad types. Each of them has its appropriate products, and should be encouraged to produce these; and the various areas, being scattered over the whole world, have complementary seasons. Of these broad types the most important are the temperate, the Trade-wind, and the monsoon.

The temperate type, as seen in Canada, has marine margins and continental interior; and these marine margins, whether dominated by snow, as in the east, or by rain, as in the west, are specially timber areas and should grow and market forest products. In 1922, Canada produced very nearly 3,000,000 cords of pulpwood and more than 1,000,000 tons of newsprint; and yet just before the War we were importing from Germany more than twice as much wood-pulp as we imported from Canada, and more than ten times as much paper.

The cleared forest is not suited either by soil or by climate to the growing of grain, but makes admirable pasture; and exports should be in small, solid, and imperishable form, *e.g.* butter and cheese. Canada and New Zealand already send us 80 per cent. of all our imported cheese, and Canada alone could supply all our needs. Off each margin, a cold sea current is exceedingly favourable to fishing, and on each margin orchard trees flourish almost as well as forest trees. Fish, fruit, forest, and dairy products are, therefore, natural exports. The dry continental interior is natural grassland with early summer rain, which is just as favourable to grain-growing as the perennial rain of the margin is to forest. Canada is now the largest producer of wheat in the world—capable of producing 400,000,000 bushels a year.

Our Trade-wind areas are partly insular and partly continental. The islands already produce the finest sugar and coffee in the world, and have almost unlimited possibilities in the way of raising fruit and tobacco. They could easily produce all the sugar and all the coffee that we need, and yet, in 1913, 90 per cent. of our sugar and 85 per cent. of our coffee came from outside the Empire.

The continental part of the Trade-wind region is mainly savana, capable of producing almost unlimited supplies of cattle and maize and tobacco, and in several areas already raising large quantities of cotton, to which the *slow* changes of Trade-wind climate are very favourable, as they are also to tobacco. For example, Nyasaland raises excellent "Egyptian" cotton on its heavy soil, and equally good tobacco on its light soil. If every native on this African savana was guaranteed a supply of "Salisbury White" maize, and was excused his hut tax if he planted a certain area under cotton, the British Empire would become the greatest producer of maize in the world, and in two years the African savana would be sending us 2,000,000 bales of cotton.

This question of cotton, however, is more important in the monsoon region. India already rules the market of the world for jute, tea, oil-seeds, and rice; and her population is of a very different type from that in Africa. India is, therefore, the only area where there can be an *immediate* increase of any product which requires a great deal of labour; but, unfortunately, India, like Nigeria, being a monsoon area, gets its heat before its rain—which greatly handicaps the quality of many crops, especially cotton. In the meantime, India raises the worst cotton in the world, so far as length of staple is concerned, and very nearly the worst in the world for yield per acre (85 lb.). But wherever cotton can be grown entirely by irrigation, as in the north-west, or where the rain comes before the heat, as in the extreme south-east, there could be a very great increase of "calico" cotton—our greatest need; and India is not troubled, as Nigeria is, with a short growing-season, which involves the natives in the necessity of providing all food crops before thinking of growing cotton.

These scattered examples may illustrate the sort of lines on which a geographical survey of the Empire would proceed. Such a survey has been already roughly made, and its results may be summarised as follows:—The Empire can produce: (1) all the wheat and oats, maize and rice, that we need, and most of the barley; (2) all the tea, coffee, cocoa, sugar, and oil-seeds (margarine); (3) all the beef, mutton, pig, and rabbit products that we need, and most of the leather; (4) all the wool, rubber, jute, and sisal, and fully half the cotton; and (5) all the most important constructional and industrial timber. In some of these cases, the Empire is already absolutely supreme; *e.g.* tea, cocoa, wool, rubber, and palm oil. All of them could be produced without a raising of price, probably with an actual lowering of it; and it is obvious that an adequate minimum of all should be produced. Only in this way can we get rid of a foreign monopoly, as in cotton, and foreign control, as in maize and meat.

Aitken's Scientific Papers.

Collected Scientific Papers of John Aitken, LL.D., F.R.S. Edited for the Royal Society of Edinburgh (with Introductory Memoir) by Dr. C. G. Knott. Pp. xxi+591. (Cambridge: At the University Press, 1923.) 30*s*. net.

THE late Dr. John Aitken bequeathed to the Royal Society of Edinburgh a sum of 1000*l*. to be expended in issuing a reprint of his more important scientific papers. The work of editing the collection was assigned by the Society to its General Secretary, the late Dr. C. G. Knott, and the present volume is the result.

Aitken's contributions to science and to its literature extend over half a century, and include about a hundred papers contributed to various societies and periodicals. The subjects ranged over a remarkably wide field. Safety-valves on steam boilers, colour vision, glaciers, thermometer screens, colours in the sky and sea, are only a few of the subjects dealt with beyond the main work which occupied his attention for more than forty years. The selection here presented consists of thirty-eight of the more important papers, and has been made with great care. The volume, which includes a brief account of Aitken's life and work, meets a real need, for in recent years the Royal Society of Edinburgh has had to reprint some of Aitken's papers more than once.

The most notable contribution made to science by Aitken was his study of dust in the atmosphere and of the physical phenomena to which it gives rise. This forms the subject of no fewer than fourteen of the collected papers. He was drawn to the inquiry from consideration of the phenomena accompanying changes of state and especially of the acceleration of such changes in the presence of "free surfaces." In his first paper, on "Dust, Fog, and Clouds," he states his main conclusion.

"Molecules of vapour do not combine with each other and form a particle of fog or mist; but a free surface must be present for them to condense upon. The vapour accordingly condenses on the dust suspended in the air, because the dust particles form free surfaces at which the condensation can take place at a higher temperature than when they are not present. Where there is abundance of dust there is abundance of free surfaces, and the visible condensed vapour forms a dense cloud: but when there are no dust particles present there are no free surfaces, and no vapour is condensed into its visible form, but remains in a supersaturated vaporous condition till the circulation brings it into contact with the free surfaces of the sides of the receiver, where it is condensed."

Aitken was not the first to reach this conclusion, for he had been anticipated by Coulier, whose results had been published five years earlier. But of the absolute independence of Aitken's work there can be no doubt, and his more extensive researches opened out the field of inquiry in such a manner that his name will always be associated with the subject. He proceeded in later papers to develop it further, to describe ingenious apparatus devised for counting the number of dust particles (or rather, condensation nuclei) in unit volume of air, and to state the results of a large number of observations, in widely different conditions, on the "dustiness" of air in houses, towns, open country, and seashore, and on mountain heights.

The present writer heard Aitken giving some of these papers to the Royal Society of Edinburgh, and had the privilege of working at the subject under his guidance. One was at first struck with the confidence with which Aitken stated his results, but there was always the note of reservation when a possible alternative was presented. Looking back on these early days, and in the light of later work, it can be seen that although his results seemed straightforward and their interpretation obvious, Aitken was troubled by the fear that something more lay behind them. This is evident from his guarded language in speaking of the arrangements for filtering dust out of a sample of air and his insistence on the readiness with which condensation takes place in the presence of alkaline salts and sulphur compounds. The fuller knowledge came later with Wilson's experiments on the condensation of supersaturated vapour upon the ions in a gas; and evidence, collected together in Dr. Simpson's recent Royal Institution lecture (NATURE Supplement, April 14), has accumulated to show that condensation at or near normal pressure takes place only on the hygroscopic dust particles. In another direction, too, Aitken's work has been supplemented. His explanation of the production of fog, especially the smoky fog of towns, was insufficient inasmuch as it (necessarily at that time) took no account of those temperature inversions at comparatively low altitudes which prevent the lateral or vertical escape of smoke-laden foggy air. But he was more nearly correct in his deduction that—

"We must remind those who are crying for more perfect combustion in our furnaces and grates that combustion, however perfect, will not remove or diminish fogs. It will, however, make them cleaner, take away their pea-soupy character, but will not make them less frequent, less sulphurous, less persistent, or less dense."

Aitken's next contribution of importance was his paper "On Dew" (1885), in which he showed that deposits of dew are produced by the condensation of water vapour rising from the soil, and that the dewdrops on grass are formed from water exuded from the pores

of the leaves when the overlying air is already saturated. His excursion into the dynamics of travelling cyclones and anticyclones forms a less fruitful but not less interesting portion of his work. By an experimental arrangement of the ingenious kind that might be expected from him, he sought to demonstrate the flow of air into a region of low pressure. Inside, and near the lower end of, a vertical metal tube, three gas jets were lit and the lines of flow of air into the updraught in the tube were then studied. The spiral motion was represented as being due to non-uniform distribution of velocity in the horizontal plane through the lower end of the tube. His theory was that anticyclonic areas supplied descending and therefore heated air to cyclonic areas, and also supplied "the cyclone with part of the tangential force necessary for producing the spiral circulation so well known in cyclones." Further, that—

"the upper winds, circling from the anticyclones, and to the cyclones, by moving more quickly, and by moving at an angle across the lower air, tend to prevent the latter rising, even although it be the lighter. The effect of this . . . is to drive the hot moist air lying near the earth's surface to the circumference of the anticyclone where it is picked up by the cyclone, and as the spirally moving cyclonic winds also tend to prevent the lower air rising, the hot moist air is swept into the front of the low-pressure area . . . and it is drawn into the centre of the depression and . . . forms the core of the cyclone."

Sir Napier Shaw has pointed out, however, that the difficulty lies in deciding whether or how far any experiment such as Aitken's really reproduces the natural conditions on the larger scale. To begin with, that portion of the atmosphere within a cyclonic area has no resemblance to a vertical column the height of which is a dozen times its diameter; its axis is most probably not vertical; it is not provided with a constant heat supply at its base; its core is almost certainly not a mass of warm moist air; and the distribution of temperature is not symmetrical about its "centre." Lastly, the whole system moves in a field of force the characteristics of which are not altogether simple. Thus, although Aitken's experiment forms an ingenious illustration of eddy motion in a fluid, his theory of cyclonic motion has not done much to advance the subject, except that it has stirred up the interest of others in the matter. Recent years have brought additional information, but the end is not yet; nor will that be reached without more extensive exploration and study of the first six or eight kilometres of the atmosphere lying over and within cyclonic areas. This, perhaps, is the greatest need of the meteorology of to-day.

Notice must be taken of the admirable sketch of Aitken's work, drawn up by the late Dr. C. G. Knott. He shows Aitken as a typical example of the private scientific inquirer—a class to whom British science owes much. With ample private means, he pursued his inquiries in his own time and in his own way, happy in freedom from those distractions which seem inseparable from the occupation of official position. He did his work because he loved it; he sought for the truth because it was "something true and good for ever, not the mere outcome of craft or expediency."

Dr. Knott's editorial work has been done with care and discrimination. But a melancholy interest attaches to it, for the date of his *imprimatur* shows it to have been the last piece of work in a long and useful life.

A. C. M.

A Zoological Tribute.

Bydragen tot de Dierkunde. Uitgegeven door Het Koninklijk Zoologisch Genootschap Natura Artis Magistra te Amsterdam. Feestnummer uitgegeven bij gelegenheid van den 70sten geboortedag van Dr. Max Weber, oud Hoogleeraar in de Zoologie aan de gemeente Universiteit te Amsterdam. Pp. 342. (Leyden: J. Brill, 1922.) 25 guilders (*2l. 1s. 8d.*).

TOWARDS the end of last year the Royal Zoological Society Natura Artis Magistra of Amsterdam issued the twenty-second number of its publication, "Bydragen tot de Dierkunde" (Contributions to Zoology), on the occasion of the seventieth birthday of Prof. Max Weber. To this large volume no less than forty-four zoologists have contributed papers on various subjects, and all thus unite, each in his own way, "to weave a small leaflet into the wreath which his adorers, friends, and pupils offer him on this festivity."

As the table of contents itself includes a considerable number of papers, it is easy to understand that we cannot possibly give a summary of each contribution in particular, for such an account would exceed the limits of the space available in NATURE. We must therefore content ourselves with mentioning those of special interest, first to the distinguished zoologist to whom the collection is dedicated, and next from the point of view of science.

No more sincere admiration of Weber's investigations of the fauna of the Dutch East Indies, and his endeavours to establish scientific collaboration between the colonies and the motherland, can be expressed than is done by Koningsberger in his partly historical, partly modern, consideration of biological research work in Dutch Asiatic colonies. The zoogeographical problems of this archipelago, which have

occupied Weber's interest since his first explorations in those regions, now nearly forty years ago, furnish the reason for Hugo Merton's contribution, a paper "Zur Zoogeographie der Aru- und Keiinseln," resuming the results of his own scientific expedition in this interesting eastern region which shows such relationship to Australian fauna.

The connexion with the fauna of British India, studied several years ago by the scientific staff of the Indian Museum at Calcutta, induced Annandale to choose as his subject a discussion of the "Marine Element in the Fauna of the Ganges." The biology of such intermediate territories between normal fresh-water and real sea-water has always been a fairly difficult subject for comparison in different areas, and this may be partly attributed to the lack of agreement in the use of the expression "brackish water."

An attempt to suggest some unanimity has been made here by Redeke: "Zur Biologie der niederländischen Brackwassertypen." Following Einar Naumann's investigations of the food-salts of the aquatic organisms, Redeke based his division of the conditions of life in brackish water on so-called chlorine spectra. These pages should be of special interest to several British zoologists. The most important divisions are:

Fresh water, up to 100 milligrams per litre.
Oligohalin (slightly brackish), 100 to 1000 milligrams per litre.
Mesohalin (brackish), 1000 to 10,000 milligrams per litre.
Polyhalin (very brackish), more than 10,000 milligrams per litre.

Several species are mentioned that are typical for each salinity. I hope British zoologists will adopt these divisions also—or propose better ones.

As the volume is dedicated to the greatest living Dutch zoologist, we are not astonished to meet a number of papers which are more or less in close relation to Weber's own fields of investigation. Thus his friend, L. F. de Beaufort, gives "Some Remarks on the Anatomy of the Melano-tæniinæ," those remarkable fresh-water fishes of Australia and part of the neighbouring archipelago. A fine Röntgen photograph shows their peculiar skull form, with the characteristic protruding mouth caused by the shape and position of the præmaxillæ.

H. C. Delsman opens here a series of studies on the development of larval fish of the Java Sea and surrounding waters, carried out in the laboratory for marine investigations at Batavia. This branch of science may have a successful future for purely scientific as well as for economic purposes, as hitherto it has been very little studied in tropical seas.

The director of the Zoological Garden at Amsterdam, C. Kerbert, contributes from his rich collection and his long experience a survey of what we know about pregnancy, birth, adolescence, and lifetime of *Hippopotamus amphibius*, observed in the different zoological gardens of Europe.

Only a short time before his death, Kükenthal drew up the results of his study of a fœtus of the Greenland Right Whale, "Die Brustflosse des Groenlandswales, *Balæna mysticetus* L." The study of these largest of mammals is a territory on which Weber and Kükenthal often met, and more than once has been the subject of sharp controversy as well as of sincere appreciation.

We now pass to those papers which are more distantly related to Weber's personality or to his own scientific work, and as such can only be regarded as the outcome of the focus of the authors' immediate interest. They fall into two chief groups: systematic and anatomical-phylogenetical. De Meyere on Javanese agromyzines; Döderlein on the genus Calliaster; de Man on marine nematodes; Eigenmann, Metzelaar, Clark, Nelly de Rooy, and Horst; indeed, they are not the least of zoologists who work as "mere" systematists. An admirable paper on "Repeated changing of Body-forms in the Course of the Phylogeny of Teleosteans" has been contributed by Abel. Here again we are astonished at the author's "biological" treatment of a subject so dead as the palæontology and phylogeny of extinct fishes.

Dollo, in his own way of discussing matters, gives a survey of some of the remarks and opposition offered against his theory of evolution, dealing here with the secondary nectonic life of Pristis and Ceratoptera and the rolling back of the curled shells of fossil tetrabranchous cephalopods. According to Dollo, these instances are but secondary adaptations accomplished along another way.

Finally, we wish to direct attention to Dubois' paper on the question whether the brains of domesticated dogs have increased in volume in comparison with those of wild races of dogs and foxes. He has worked out accurately the results of his measurements and weighings, and concludes that, contrary to the usual opinion that domestic animals should have increased in brain weight, tame dogs at least are provided with smaller brains than their wild congeners.

From the fourteen contributions to this work written in the English language reference can be made only to that of R. F. Scharff "On the Origin of the West Indian Fauna"—a complicated problem.

The volume is attractively illustrated, the first full-page being a fine portrait of Weber. Paper, print, and illustrations are fully up to the usual standard of the publications of the firm of E. J. Brill, of Leyden.

W. G. N. van der Sleen.

American Chemical Monographs.

(1) *The Origin of Spectra.* By P. D. Foote and F. L. Mohler. (American Chemical Society Monograph Series.) Pp. 250. (New York: The Chemical Catalog Co. Inc., 1922.) 4.50 dollars net.

(2) *The Properties of Electrically Conducting Systems: Including Electrolytes and Metals.* By Prof. Charles A. Kraus. (American Chemical Society Monograph Series.) Pp. 415. (New York: The Chemical Catalog Co. Inc., 1922.) 4.50 dollars.

(3) *Glue and Gelatin.* By Jerome Alexander. (American Chemical Society Monograph Series.) Pp. 236. (New York: The Chemical Catalog Co. Inc., 1923.) 3 dollars.

(4) *Catalytic Action.* By K. George Falk. Pp. 172. (New York: The Chemical Catalog Co. Inc., 1922.) 2.50 dollars.

(1) THE monograph on "The Origin of Spectra" has been well written by highly qualified authors. The subject is not an easy one to handle, especially in view of the fact that the mathematics involved in the quantum theory of spectra is so difficult that only those who have specialised in advanced mathematics can hope to follow it. The utmost that can be done, therefore, in presenting the subjects to chemists is to try to give to them a clear picture of the general nature of the problems and of the solutions which have been found for them, without attempting to display the intermediate stages of the work.

Under these conditions, it is no serious reflection upon the authors of this monograph to say that Prof. Bohr has achieved a greater measure of success in the difficult, if not almost hopeless, task of explaining his theories to readers who are unable to understand the arguments on which they are based. This monograph is, however, much more experimental in character than Bohr's "The Theory of Spectra and Atomic Constitution," and is liberally provided with photographic reproductions of spectra of the most diverse types; indeed, in the matter of successful illustration this book may be compared with the publications of Prof. R. W. Wood, some of whose photographs are reproduced in the present volume.

As a general conclusion it may be said that the authors of the monograph have rendered a valuable service to chemists by bringing together so much information in reference to spectroscopy; but that they have probably overrated the mathematical and physical equipment of their readers. The result is that even a physical chemist, with a keen interest in spectroscopy, is likely on reading this book to feel that he is being carried—no doubt by highly competent swimmers—into rather deep water, where he is only occasionally allowed to touch bottom, or to exercise his own limited powers of swimming.

(2) Prof. Kraus deals with a subject with which physical chemists are much more familiar. His book professes to cover the properties of electrically conducting systems in general; but, in actual fact, metallic conductivity and gaseous conductivity occupy so small a portion of the volume that the monograph is really concerned only with liquid electrolytes, although it contains a final chapter on "The Properties of Metallic Substances."

Earlier writers on electrolytic conductivity, especially those of the German school, have erred in paying attention almost exclusively to aqueous electrolytes. This inevitably leads to a distorted view of the phenomena, since properties which are quite exceptional are accepted as normal if they happen to exist in aqueous solutions. Prof. Kraus, as a distinguished research-worker in the field of non-aqueous solutions, is particularly well qualified to give a broader view of the phenomena. His presentation of the subject, therefore, leaves the reader with the feeling that, under the guidance of the author, he has surveyed the whole width of the field, instead of being conveyed across it on a narrow stream of conductivity-water with such high banks that the greater part of the field is shut out from his view.

(3) Mr. Alexander's book on "Glue and Gelatin" is, in the opinion of the reviewer, of a much lower standard than the two preceding volumes. The author has already written a book on "Colloid Chemistry," but is not well known to English readers. From the book itself it is difficult to know whether the author is a colloid-chemist who has taken an interest in the manufacture of glue, or a glue-chemist who has taken an interest in the theory of colloids. In any case the monograph lays itself open to criticism by the fact that it is neither a complete technical handbook nor a satisfactory theoretical treatise.

It is indeed difficult to picture the mental attitude of the author of a technical work who finds it necessary to warn his readers of the importance of possessing "minds flexible enough to fit all the facts of Nature": or of the writer of a book on glue who proceeds to inform his readers that "the decimal in the atomic weight of hydrogen 1·008 represents electrons." Although the work contains a considerable amount of information, as well as many quotations from papers to which references are given, it is very badly put together. In this case at least the American Chemical Society has made itself responsible for a work which ought to have undergone drastic revision before being issued.

(4) Dr. Falk's book on "Catalytic Action" has not been written under the authority of the American Chemical Society, although it is issued by the same publishers, and it differs in style from the monographs reviewed above only in the absence of the Society's imprint and general introduction. Dr. Falk has recently published a book on "Chemical Reactions" in which he lays stress on the formation of intermediate addition-compounds; he represents these by enclosing the formulæ of the reacting substances in large square brackets, similar to those used by Werner to represent co-ordinated complexes. The present volume is in the main an interpretation of the phenomena of catalysis on the basis of this theory.

The theory itself lacks the preciseness of Werner's theory of co-ordination, and does not lead to any marked simplification of the task of explaining the phenomena of catalysis. In this respect it is indeed less helpful than the crudely mechanical theories of adsorption which have so clearly proved their utility in recent years, and are described in the tenth chapter of this monograph. The author states in his preface that he has not attempted to cover the whole field of catalytic reactions, but has discussed only sufficient cases to illustrate his own particular point of view. Since this point of view is not especially helpful, the ordinary student would probably be well advised to use a text-book written from a less specialised aspect; but research-workers on catalysis may well find fresh inspiration in a novel way of looking at familiar facts.

Characters and History of the Ferns.

The Ferns (Filicales) Treated Comparatively with a View to their Natural Classification. By Prof. F. O. Bower. Vol. 1: *Analytical Examination of the Criteria of Comparison.* Pp. x+359. (Cambridge: At the University Press, 1923.) 30*s.* net.

THE publication of the present volume is of peculiar interest to all who seek to understand the inter-relationships of living organisms. Consisting, as it does, of some 360 pages of beautifully produced and liberally illustrated matter, this book is indeed a literary effort of which both author and publishers may well be proud.

It has been Prof. Bower's intention to present not only a reasoned statement of the relative value of the criteria on which the systematic grouping of the ferns must for long be based, but also to indicate for them probable relationships with other primitive phyla, and thus to render the comparative study of their phylesis contributory to still wider views on the descent of land-living organisms. The present volume deals primarily with the criteria of systematic comparison themselves. Presenting as it does for the first time in the history of the literature of plant-systematics a fully co-ordinated and closely reasoned statement on the values ascribed to the characters considered, it forms a conspicuous landmark in the progress of systematic thought and writing.

On the criteria drawn from the widest study of external form, cellular segmentation, leaf venation, the vascular system of the shoot, dermal appendages, the position and structure of the sorus, indusial protections, the characters of the sporangia and spores, spore-output, the morphology of the prothallus, the position and structure of the sexual organs, and the embryology of the sporophyte, the author's rebuilding of the systematics of the ferns in the second volume will largely rest. It is not too much to say that in this book Prof. Bower has valiantly endeavoured to formulate anew standards of phyletic comparison whereby a new and more reasonable order will arise out of the chaos to which fern-systematics had been reduced. A chapter is devoted to each criterion considered, and a comprehensive and carefully chosen bibliography is in each case appended, chosen with the author's full knowledge of the literature of his subject.

Varied as are the ways whereby we arrive at our conclusions, our most absorbing interest, and indeed our ultimate aim in the study of living organisms, lie in the determination of their inter-relationships. It is safe to assert that for the past generation the only method open for a reasonable understanding of the phylesis of any group of organisms has been the morphological method. This Prof. Bower has followed with admirable persistency and foresight throughout a lifetime of active research. That the results have fully justified the means cannot for a moment be doubted. To arrive at a reasonable grouping of the ferns from the comparative study of their characters of form, structure, and reproduction has been the avowed aim of the author for many years. That the meaning of the characters themselves expressed in form and structure still escapes us will be readily granted. For many who have not followed his phyletic method, the absence of a final interpretation of structural characters may seem cause for delay in the acceptance of the relative value of the characters discussed, and indeed of any wide application of the conceptions of the relative primitiveness or advancedness at which the author has arrived. Instinctively, one revolts against the idea that hairs must be the expressions of relatively primitive characters, while scales, on the other hand, are indicative of advance, even though the author has conducted with consummate skill a special pleading of the case, supported on broad grounds by the illuminating evidence of fossil-history. That primitive ferns

were dominantly hairy is universally accepted on the fossil evidence itself, but that hairiness in a living organism—which on other grounds is considered advanced—may be viewed as a relatively primitive character seems unjustifiable, especially in the absence of any intimate understanding of the meaning of either hairiness or scaliness in any living fern.

The case is similar, and indeed must be so, with all the characters concerned, considered as they are by the author on the broad basis of structural comparison alone. It is so, for example, in the consideration of the vascular system of the axis, the venation of the leaf, and the gametophytic generations; for although we are now in possession of the fullest knowledge of the distribution and structure of vascular tracts and of the organisation of the sexual generation of many ferns, we still know nothing of the meaning of conductive tissue in the ontogeny of any organism, or of the true values to be assigned to the gametophytes of any fern which may figure in a systematic discussion.

In the hands of a less skilful writer and pleader the conceptions of "biological probability" which underlie the author's treatment of structural characters might seem less alluring than they do in the pages of this volume. The weakness of the morphological method lies indeed in its inherent inability to explain the characters considered. It must always be so, until a closer co-operation has been secured and persistently maintained between morphological and physiological investigators. Its strength lies in the knowledge that for long it must remain the sole avenue to wide generalisations on phyletic relationships. To its weaknesses and to the tentativeness of the conclusions secured by morphological study alone, the author of this work is as fully alive as is any student of phylogeny who would arrive, at some distant period, by physiological inquiry at a reasonable understanding of any life-process.

The very doubts and fears which the consideration of this book must naturally arouse for those who have not employed the author's methods are, however, integral parts of its purpose. We are on the eve of new departures in morphological inquiry, in which a closer alliance between the pure physiologist and the morphologist will be secured. It is good, then, to have this treatise at this time providing the sum of knowledge in a branch of biological science so admirably condensed, and the philosophy which has grown with it so skilfully and so clearly presented. The day of the formal morphologist is past: the day of the causal morphologist is already with us. It may yet be possible to present a work in which a chapter on "the habit and habitat of ferns" will form a satisfying conclusion to the treatise as a whole, for these are the expressions of the sum of the characters with which the author has dealt so ably.

Whatever will be the fate of the classification which the second volume of this treatise is to provide, the present volume will stand as a classic in the presentation of the thought and work of a school of investigators who for a generation have made history in biological inquiry. The pages of this book should be read and re-read by every student of descent, and its matter will be undoubtedly considered as a statement of structural fact which has seldom been surpassed in the literature of the natural sciences for clarity and just judgment.

Our Bookshelf.

Contributions to Embryology. Vol. 14, Nos. 65-71. (Publication No. 277.) Pp. iii + 162 + 15 plates. (Washington: Carnegie Institution, 1922.) 3.50 dollars.

AMONG noteworthy papers on the development of the circulatory system by E. D. Congdon, H. H. Woollard, Florence R. Sabin, and others, this volume contains an important contribution by Charles A. Doan to the solution of the problem of the bone-marrow circulation. His method of investigation was general injection, under a pressure of 130 mm. of mercury, with an Indian-ink solution, of the vascular system of about forty pigeons. By this means he claims to have brought to light the existence of an extensive capillary plexus connecting the branches of the sinusoidal, venous elements, arranged in tufts, which probably form the active, functioning vascular bed of the bone-marrow.

It is suggested that the normal state of these blood-channels, which must be studied in hypoplastic marrows, is one of collapse. This view the author correlates with his conclusion that the vascular system of the bone-marrow is a closed system, and with Drinker's discriminating statement that red cells are apparently found outside the blood-stream, and enter the moving current as a result of growth pressure, but that their extravascular origin is not implied by this presentation of the facts. It is clear that the capillary system described would add to the endothelium of the larger vessels the amount represented in a close and extensive network throughout the marrow. In the light of this, Sabin's work on the origin of blood-cells in the chick embryo is reviewed. The *venous sinusoids* of the author's text are the *venous capillaries* of most other writers. There is much to recommend the new term. Another point of interest is the author's description of the relation between the vessels of the marrow and those of the periosteum, and of the compact tissue of the diaphysis.

Die Vegetation der Erde. Herausgegeben von Prof. A. Engler und Prof. O. Drude. XV.: *Die Pflanzenwelt der bolivischen Anden und ihres östlichen Vorlandes.* Von Prof. Dr. Th. Herzog. Pp. viii + 258. (Leipzig: W. Engelmann, 1923.) 27,000 marks.

THE first part of the work under notice deals with the physical geography of Bolivia, a country comprising both high Andean tableland and moist tropical forests. This is preceded by a short account of the various

botanical expeditions to Bolivia, one of the most important being that of Weddell, which led to the publication of his classical "Chloris Andina." Dr. Herzog has made two expeditions himself, and the book before us is largely based on his own extensive travels and observations.

The second part is divided into chapters dealing with the several groups and families of plants which comprise the flora. The characteristics of the formations are described and a brief account of the different ecological regions found on the west and east sides of the Cordillera and in the high Andes is also given.

In the third and largest part, the types of vegetation and the history of the flora are more fully dealt with, and throughout the book there are numerous good text figures showing the different types of vegetation from the low lands of the Gran Chaco, the eastern edge of the Cordillera, the Savanna region of Santa Cruz de la Sierra, and the vast high Andean region which has so remarkable a flora. There is also a useful short chapter on the cultivated plants of Bolivia, and three vegetation maps and plans conclude the volume. Throughout the book the author indicates the affinities of the flora to the floras of adjacent and distant countries.

(1) *A Text-Book of Dental Anatomy and Physiology.* By John Humphreys and A. W. Wellings. Pp. viii + 323. (London: E. Arnold and Co., 1923.) 16*s.* net.
(2) *A Manual of Human Anatomy for Dental Students.* By R. Bramble Green. Pp. xi + 263. (London: Benn Bros., Ltd., 1923.) 18*s.* net.

Within its necessary limitations, each of these books is admirable. Half of (1) is devoted to comparative dental anatomy, being a well-written and straightforward account of an intricate subject which may be expected to contribute considerably to the education as well as the instruction of dental students. If it fails at all it is when too great a desire for the brief and definite leads to such statements as that "the adoption of the erect attitude led to the perfecting of the hand, that marvellous piece of mechanism by which man's progress became assured, and in consequence of this came the increase in cranial capacity and intellectual development." Such a statement, moreover, does not represent current views. The less general matter is excellent.

(2) Mr. Green has filled a gap in the series of text-books. His account of the salient features of human anatomy is well arranged and well illustrated, and he has shown great discretion in necessary omissions. The ligaments called "alar or check" in the text are marked "accessory" in the corresponding figure; but mistakes are few.

Die Pfeilgifte: nach eigenen toxikologischen und ethnologischen Untersuchungen. Von L. Lewin. Pp. xi + 517. (Leipzig: J. A. Barth, 1923.) Grundzahl: 13 marks.

Dr. Lewin's monograph on arrow poisons is one which neither students of toxicology nor those who are interested in primitive science and methods of warfare and the chase can afford to neglect. Its comprehensiveness and careful attention to minute detail are such that it is not surprising to learn that it is the product of some thirty years' study and research. In an introductory chapter he surveys briefly the early use of poisoned weapons, which were well known to the ancients and may, the author thinks, go back so far as late palæolithic times, if, that is, his explanation of certain grooves in Magdalenian bone implements is correct. He then goes on to describe in detail the various forms of poison, both animal and vegetable, in use in all parts of the world, including Europe in early historic times. Not only does he deal with their preparation, but he also considers their chemical composition and gives the result of experimental observations of their effects and the length of time in which these effects are produced. Special attention has been given to the well-known Upas or Ipoh poison of the Indonesian area and the curare of South America, and in both cases interesting accounts of these poisons are quoted from early travellers.

A Naturalist in Hindustan. By R. W. G. Hingston. Pp. 292 + 10 plates. (London: H. F. and G. Witherby, 1923.) 16*s.* net.

Imbued with the spirit of Fabre, and possessing much of his ingenuity and accuracy, Major Hingston gives a fascinating account of some of the ants, spiders, and dung-burying beetles that he has watched and subjected to various experiments in a small patch of jungle in the Fyzabad district. Of the many good things that he sets before us perhaps the most interesting are his observations on the power of communication with one another that is possessed by ants, and on their sense of direction. That an individual Phidole ant having found treasure afield is able on returning to the nest to send forth direct to the treasure and unescorted an army of its fellows, compels our wonder. The author, however, shows convincingly by reference to other species how in all probability this amazing faculty has been evolved from very simple and perfectly intelligible beginnings:—guidance of one follower by actual touch along the whole route is the starting point; progress towards the complex phenomenon exhibited by Phidole depended on successive refinements of the olfactory sense. That sense of direction is possessed seems proven by the experiments cited; but "it is quite inexplicable to us."

La Chimie et l'industrie. Numéro spécial, mai 1923. (Congrès Exposition des combustibles liquides.) Pp. 852 + xcii. (Paris: 49 rue des Mathurins, 1923.) n.p.

La Société de Chimie Industrielle organised in the month of October 1922 an International Congress on Liquid Fuels, which appears to have fulfilled the objects of the Society. A very large number of scientific and practical problems, due for solution, were discussed by the members of the Congress. The results of their labours are seen in the 800 pages of this volume, which in effect becomes a text-book illustrative of current procedure in the winning and in the utilisation of liquid fuels. Much is said of the prospect of future supplies, but little can be known with certainty in view of the doubtful duration of the yield of known wells and the unknown possibility of the discovery of further oil fields. So small an area of the world has yet been surveyed, and so little is known of the origin of the various oils, that the time is not yet ripe for the formation of broad policies. A watchful, waiting attitude is the only scientific one.

Letters to the Editor.

Correlation of Upper Air Variables.

I DO not see that Prof. Mahalanobis (NATURE, September 1, p. 323) has given any good reason for the statement that the correlation coefficients that I have obtained from the English balloon ascents are to be taken as the upper limit of what is possible, excepting that Capt. Douglas working on a different system in one specific instance has obtained a lower value. I freely admit they may be wrong; unless one has a very large sample one always has to reckon with the casual error of a correlation coefficient, but there seems no reason why I should not equally well accept Dr. Chapman's conclusion that they are too low.

Taking Prof. Mahalanobis's equation (1) (Memoirs of the Indian Meteorological Department, vol. xxiv., pt. ii., p. 12), transposing it somewhat, and re-arranging, we get the following expression for the correction for the observational errors:

$$\frac{s_a}{s_b}\left\{r_{ax}r_{x_1y_1} - r_{ay}\right\} + \frac{s_b}{s_y}\left\{r_{by}r_{x_1y_1} - r_{bx}\right\}$$

$$+\tfrac{1}{2}\left\{\frac{s_a^2}{s_b^2}r_{x_1y_1} + \frac{s_b^2}{s_y^2}r_{x_1y_1} - 2r_{ab}\frac{s_a s_b}{s_x s_y}\right\}$$

$$-\tfrac{1}{2}r_{x_1y_1}\left\{r_{ax_1}\frac{s_a}{s_x} - r_{by}\frac{s_b}{s_y}\right\}^2$$

where x and y denote the true departures from the mean, x_1 and y_1 the observed departures, and a and b the errors.

Let us take the special case of the correlation between pressure and temperature at a fixed height between 4 and 8 kilometres. Here $r_{x_1y_1}$ is equal to 0·85 and the ratios s_a/s_x and s_b/s_y are known to have a value of about 1/5.

Substituting approximate numerical values the correction is

$$0{\cdot}20(0{\cdot}85r_{ax} + 0{\cdot}85r_{by} - r_{ay} - r_{bx}) + 0{\cdot}04(0{\cdot}85 - r_{ab}) - 0{\cdot}02(r_{ax} - r_{by})^2.$$

Owing to its comparatively high numerical coefficient the first bracket is the important one, and a negative correction requires that r_{ax} and r_{by} should be negative and r_{ay} and r_{bx} positive. I can see no reason why the correlation values should be anything but casual; they will certainly be small. Moreover, x and y are positively and highly correlated and therefore r_{ax} and r_{ay} are likely to have the same sign; so are r_{bx} and r_{by}, hence it does not seem likely that the term can supply a large correction either positive or negative.

In the second bracket the coefficient r_{ab} is certainly positive for the special case where a and b refer to the errors of temperature and pressure at about 6 kilometres height. This is apparent because y_1 is calculated by Lagrange's formula and a positive value of (a) increases the value of y_1 and therefore increases (b), but the casual error of y_1 due to faulty calibration or incorrect working up will prevent the correlation between a and b being as high as 0·85 and the term will be positive. The third bracket is the square of a small quantity multiplied by 0·02 and is insignificant. Thus it appears probable that on the whole the computed correlation coefficients are somewhat too low.

There can be no reasonable doubt that the correlation between certain variables in the upper air is very high, and any theory of the genesis of cyclones and anticyclones to be satisfactory must account for such correlation.

I should like to add that I have never thought that the seat of atmospheric disturbances was in the stratosphere, but, since upper air observations have been available, have held that the winds of the general circulation in the upper part of the troposphere are responsible for the formation and maintenance of cyclones. This fits in satisfactorily with the known variations of temperature.

W. H. DINES.

Benson, Wallingford, Berks.

Greek Orthography in Scientific Names.

IT is difficult, as correspondents in NATURE have noted, to preserve orthography in scientific names derived from the Greek. A good example of the confusion which has been allowed to become inevitable occurs in the similarity of the generic title of two very dissimilar shrubs. *Chionanthus Virginica* has been named from χιών—snow—because of the masses of white blossom it bears at midsummer; while *Chimonanthus fragrans*, flowering in midwinter, ought to be written *Cheimonanthus*, from χειμών, winter. To each of these Greek generic names a Latin adjective has been tacked, which serves to distinguish the species, but may offend the scholar.

HERBERT MAXWELL.

Wigtownshire, N.B.

X-Rays and Crystal Symmetry.

IT has long been recognised that angular measurements do not always carry one beyond a determination of the system, and that other methods of investigation are needed if the crystal is to be assigned to its class of symmetry. But different methods do not always give the same result, so that some principle of discrimination has to be adopted. In the past the principle universally applied has been that of greatest common measure, the crystal being correspondingly relegated to the highest class, the symmetry of which is common to the various symmetries observed (in most cases this leads to the lower of two observed symmetries, since the symmetry of one is generally wholly contained in that of the other). It must be noted that all class assignments are provisional and liable to modification (necessarily in the direction of lower symmetry) as new evidence is forthcoming.

The above symmetry has hitherto always been regarded as the true symmetry of the internal structure. This view has been somewhat questioned by E. T. Wherry (*Amer. J. Sci.*, 1922, vol. 4. p. 237) and repudiated by R. W. G. Wyckoff (*ibid.* vol. 3. p. 177; vol. 4. p. 469). It is much to be regretted that considerations of space prevent any discussion of Wherry's paper, for it is in many ways suggestive. The issue raised by Wyckoff is, however, more clearly defined. As a result of a renewed X-ray examination of sal-ammoniac he finds that there is no possible model which will simultaneously satisfy Tschermak's symmetry, deduced from surface studies, and the X-ray data (a model can be found to agree with either of two higher symmetries, the ambiguity arising from an impossibility of placing the hydrogen atoms on account of their small scattering power). This leads to an entirely new definition of symmetry, as being that of the constituent parts (the atoms) as revealed by X-rays. The evidence of such surface phenomena

as face development, etch figures, and the like, is discussed and finally dismissed as untrustworthy—apparently on the sole ground that some crystals are known to exhibit different geometrical symmetries when grown or dissolved under different conditions.

An examination of Wyckoff's and Tschermak's papers would seem to leave no doubt concerning an actual clash between the two symmetries, but as Wyckoff's explanation is quite unacceptable I would discuss it here and add a few suggestions, which may contribute towards an eventual solution to a problem of great complexity.

The question, whether symmetry of structure (there is no other real symmetry) can be deduced from surface observations, revolves round the following typical case, in which observations on etch figures can well be omitted, for dissolution is the inverse of growth. Among the faces exhibited by a certain orthorhombic substance are those of a right tetrahedron, sometimes but not always accompanied by those of the correlative left tetrahedron. In the former case the symmetry appears to be holoaxial, the crystal belonging to the category of enantiomorphous figures; while in the latter case the symmetry is apparently holohedral, and the crystal is identical with its mirror image. Even in the case of such apparently ambiguous evidence the crystallographer believes he can determine the correct symmetry of structure.

In any crystal having the lower symmetry, similar directions occur in sets of four, geometrically expressible as normals to a tetrahedron. This offers a simple structural interpretation of the observed fact that if the conditions at the surface are suitable for the appearance of one facet, the other three are simultaneously developed. In other words, the structure is controlling the surface. But the conditions may simultaneously be favourable for a revealment by the structure of another set of morphogenetic directions—with the production of the left tetrahedron. The definitive choice of the lower symmetry is still seen to afford a simple correlation between structure and surface. Now consider the implication of the selection of the higher symmetry, demanding the structural subsistence of similar directions in groups of eight instead of four. The simultaneous appearance of the two tetrahedra is accounted for, but not the occasional development of the right tetrahedron alone (or alternatively of a left tetrahedron alone, if this ever occurred). There is no longer any simple explanation for a tetrahedral development, as opposed to a development of four facets at one end of the crystal (hemimorphic), or of three facets at one end and the fourth at the other. The possibility of correlating form and structure vanishes just as utterly as if the crystal were bounded by an irregular or curved surface.

Now the above substance, like thousands of others, shows no trace of curvature but obeys Haüy's Laws of Symmetry and of Simple Multiple Intercepts. Some crystals are, however, known which are partly bounded by plane and partly by curved faces, and the question naturally arises whether such curved boundaries admit of a simple structural interpretation. Fortunately, the invention of the two-circle goniometer permits of the exact exploration of a curved surface, and a recent observation in the Oxford laboratory may now be put on record. A substance closely allied to the one already discussed, in addition to plane facets of negligible symmetry import, exhibits large curved tracts arranged tetrahedrally. Moreover, there are two kinds of crystal, the curved tetrahedron of one being the mirror image of that of the other. If the crystals were mixed together, they could be separated by hand. It is evident that the apparently irregular boundary of certain crystals is being reduced to the same rule of law and order as is obeyed by the plane-faced crystals of the text-books.

Such results as the foregoing are held by a growing body of X-ray workers to have no exact structural implication, being contaminated, as it were, by the non-crystalline influence of the surrounding fusion, solution, or vapour. It therefore seems desirable to press the argument home into the structure. Exactly seventy-five years ago a young crystallographer was examining a problem that had long vexed several Academies of Science. The problem had in fact been pronounced insoluble only three years previously, but the tiny tetrahedral facets, occasionally observed in certain crops of crystals and not in others (a fact I know from experience), proved sodium ammonium "racemate" to be an impostor, being in fact a conglomerate of *d*- and *l*-tartrates. In this way Pasteur showed there is something of unimpeachable integrity on the surface of a crystal: something which when properly interpreted can be made to found a new province of a science dealing with liquids and vapours.

But this is not all. A later (as also an earlier, but forgotten) advance in the classification of crystals led to the recognition that out of thirty-two classes of crystal symmetry, there are eleven enantiomorphous classes: namely, the asymmetric class of the anorthic system, the tartaric acid class of the monoclinic, the Pasteur class of the orthorhombic, and two classes in each of the rhombohedral, hexagonal, tetragonal and cubic systems. It follows indubitably that every substance which is optically active in solution belongs to one of those classes. Happily, the most important systems statistically are the first three mentioned, and a recent count has shown that some 420 structures (an isomorphous group being regarded as one structure), representing 93 per cent. of optically active substances on the crystallographic record, are thus definitely known as to their class of symmetry. There are possibly two thousand more, lying indetermined in the specimen cupboards of the chemist for want of a crystallographer on the staff to examine them. (Parenthetically, I would point out that Shearer's rule could well be tested by an X-ray examination of those substances, which in solution have a truly asymmetric configuration. If, for example, the anorthic tetrahydrated acid strontium tartrate were found to contain more than one molecule to the unit of structure —or seignette salt more than four—the rule would be infringed.)

Unfortunately the Pasteur generalisation is not applicable to all crystals, so that a careful examination of the surface, eked out by a determination of certain physical properties, is still demanded for the great majority of substances, namely, those inactive in solution and, owing to a certain limitation, those which are only active in the crystalline condition.

The above will, perhaps, be sufficient to show that surface studies lead towards a real knowledge of crystal symmetry, provided they are interpreted by the principle of greatest common measure. In individual cases the knowledge may not be complete at the outset (every determination being in a sense provisional). It may have to be modified with accretion of evidence, in which connexion it is a highly significant fact that whenever there has been such a modification in the past, as a result of a study of such structure properties as pyro-electricity or optical activity, the modification has always been towards a lower symmetry, *i.e.* towards a symmetry which experience proves might equally well have been offered (if only on one occasion) by the surface, if the crystal had been grown or dissolved under a greater variety

of conditions. On the other hand, the symmetry demanded by the X-ray work on sal-ammoniac is higher than that of the crystallographer. It is, therefore, not the crystal symmetry (the complete physico-chemical symmetry on which crystallography and its offshoot stereochemistry are based) but a pseudo-symmetry—a phenomenon with which the crystallographer is familiar in other connexions. It may accordingly well be termed X-ray symmetry, in order to distinguish it from other pseudo-symmetries.

Now, whatever may be the true cause of this X-ray symmetry, the explanation given by X-ray workers is singularly unconvincing. So far from harmonising a previously organised body of fact and interpretation of proven worth with the new results, the explanation relies wholly on the data obtained from the X-ray tube, and discounts the value of surface evidence, almost on principle—for however ambiguous surface evidence may be in certain crystals, it cannot be fairly held to apply to sal-ammoniac, in which plane faces of growth, the run of their striations, and the orientation of etch figures all demand the same class of symmetry. It is surely obvious that the real explanation must take equal cognisance of all well-established facts, including those collected by the aid of the goniometer, microscope, polarimeter, and, last but not least, the test-tube, all such facts being apparently equally precious in this province of crystal symmetry. The problem is to evaluate the results from all these instruments without unduly elevating or depressing this or that section. My own view is that the ultimate solution awaits the discovery of a new method, which shall tell us as much about the chemical aspect of crystal structure as the X-ray method does about its physical side. Thus warned, a reader will not expect too much from the following paragraphs.

As a preliminary, it seems necessary to clear up a widespread misapprehension concerning the results of X-ray investigation. It has not infrequently been stated that the recent work on organic compounds has proved the existence of the molecule in the crystalline condition. I do not know how this misapprehension arises, for a perusal of Sir William Bragg's original paper, in this domain, shows that the molecule is assumed as a working hypothesis. The real position is that the X-ray method can scarcely ever be expected to prove molecular structure. It is now generally accepted that the origin of X-rays (as also the seat of their diffraction) lies near the nucleus, and not in the few peripheral valency electrons which provide an occupation for the chemist. The X-ray method has the defect of its qualities: in revealing the atomic positions in a crystal, it ignores the molecular aspect completely. In the case of naphthalene the method reveals the presence in the crystal of pockets, each containing a mass of material having the composition $C_{20}H_{16}$ (if anything, then, in this case it reveals polymerised molecules). The interpretation naturally takes a molecular form, because any other would be chemically absurd; but so far as anything of the nature of chemical "bonds" is concerned (or of a union of certain atoms into a molecule) it is, relatively, a waste of time to appeal to the X-ray bulb. The proper appeal is to the test-tube.

A similar remark applies to the typical inorganic case of sodium nitrate. The crystal model of the X-ray analyst allows an interpretation of a structure, which has been electrically resolved into sodium and nitrate ions. But it might also be interpreted as a fine mixture of sodium, nitrogen, and oxgyen, or even as an ionised sodium nitrite plus oxygen, in which the latter strives after geometrical symmetry and succeeds. There can of course be little doubt that we are dealing with the first alternative, because it is possible to crystallise a solution to dryness, and redissolve the salt without any appreciable evolution of nitrogen or formation of nitrite. It may be added that although ionisation of a crystal salt into electrolytic parts is extremely probable, it has not yet been proved by the X-ray method (Debye and Scherrer's work on lithium fluoride being generally held, in particular by W. L. Bragg, to be inconclusive).

In this purely atomic reaction of molecular matter to X-rays (proved to the hilt by the pioneering work of Barkla and later by Moseley) there would seem to lie a possibility of obtaining a higher symmetry than by the physico-chemical method of surface studies. The rôle played by the physicist's atom in his statement of symmetry is that of a sphere. This may be true so far as X-rays are concerned, but scarcely of the crystal, for valency forces must be taken into account. The question therefore arises whether the replacement of a sphere by a humped surface (or, alternatively stated, whether a consideration of the movements of valency electrons) will serve to degrade the symmetry, not merely of the individual atoms (as it must) but also of the structure as a whole (as it might). If this is found to be the case there is an obvious explanation of a pseudo-symmetry, obtainable by the X-ray method.

An examination of this problem shows that no lowering of symmetry can result from single valencies (I have, then, no explanation to offer for sal-ammoniac), but with the double bond (the double sharing of electrons), which first becomes possible with a divalent atom, the symmetry may, indeed, be degraded, always provided that the atom occupies a "specialised" position in the structure, *i.e.* a position in which it may be the seat of centro-symmetry or intercepted by a plane or axis of symmetry. In a crystal of sodium nitrate, for example, we have probably to deal with Na^+ and NO_3^-. If the oxygen be monovalent, or divalent with the double bond lying in the basal plane of the crystal, the symmetry is still that of the atomic crystal of the physicist; but if the double bonds be arranged in a manner suggested many years ago, without any reference to X-rays, by J. E. Marsh and myself (J. Chem. Soc., 1913, vol. 103, p. 845), the NO_3^- group acquires the symmetry of quartz, and so does the crystal as a whole (the new "space group" or point system being: Fedorov, 46 *s*; Schoenflies, D_3^7). Such a crystal would be indistinguishable by the X-ray method from the atomic crystal of the physicist, but would presumably betray its lower symmetry, when allowed to grow or dissolve in its solution. A similar theoretical possibility holds, of course, with the calcite group, the extra electron given up by Ca^{++} making up the corresponding deficiency in an atom of carbon as compared with an atom of nitrogen.

The real state of affairs is evidently not as described above, for the symmetry of the calcite group and of sodium nitrate is not that of the quartz class. It does not necessarily follow, however, that the crystal is exactly as it has been left by X-ray workers. It may be a "racemic" substance, consisting of alternate basal strata of *d*- and *l*-carbonate or -nitrate groups, interlaminated by charged calcium or sodium atoms. Examination of the new model shows such a crystal to have both the correct symmetry and the same space group as the purely atomic model (Fedorov 47 *h*, Schoenflies D_{3d}^6), but with a crystallographic vertical translation equal to twice the old value. From the X-ray point of view, however, the vertical translation would be as before, for X-rays would scarcely appreciate the fact that they are dealing with enantiomorphous groups of valency electrons. The

case is not analogous to racemic acid, for there is no enantiomorphism of the grossly material nuclei or inner swarms of electrons.

It need scarcely be added that the optically active sodium chlorate (or bromate) follows the above scheme and is in agreement with recent X-ray atomic models. The instantaneous racemisation on dissolution may well be attributed to the delicate nature of a purely electronic type of enantiomorphism.

The above suggestions are possibly open to the objection that they are too elusive to be put to an experimental test. This leads me to suggest material for future investigation, which may help towards a decision. The rhombohedral dithionates of calcium, strontium, and lead are usually quoted as having four molecules of water of crystallisation, thus, $PbS_2O_6, 4H_2O$. If this is really true, it would seem to follow that the crystal unit must contain six, if not twelve or even twenty-four, molecules of the salt, and that no successful elucidation is to be expected with present-day X-ray technique. But a rhombohedral crystal with four instead of three or six molecules of water almost amounts to a contradiction in terms, and the early analyses of these salts (ignition to an anhydrous sulphate) are perhaps not conclusive. A particularly simple crystal structure is consistent with a hexahydrated salt; in fact any eventual proof of a four-unit cell would determine the water content as securely as a chemical analysis. It is therefore conceivable that the structure is modelled on the calcite pattern (four molecules to the Bragg unit) according to the following scheme :

$$\ldots [6H_2O]Pb^{++} \ldots O_3S^{-}\text{——}^{-}SO_3 \ldots [6H_2O]Pb^{++} \ldots$$

and that we shall have an X-ray pseudo-symmetry, the atomic assemblage appearing to have the symmetry of calcite, while the crystal structure has the symmetry of quartz (the crystals are optically active, but not the solution). The rhombohedral (or hexagonal ?) anhydrous potassium salt may, perhaps, follow similar lines, but the crystallography is somewhat obscure.

No good purpose would be served by following out the consequences of a deformation of the RO_3 group into lower systems of crystallisation. Nor need the case of an RO_4 group be discussed, as it does not seem to offer any likelihood of pseudo-symmetry.

As previously indicated there is no such possibility of pseudo-symmetry as the above, when no atom, ion, or molecule occupies a specialised position in the structure. None is therefore to be expected in any of the 420 optically active structures previously mentioned. In theory, then, we have here another possible way of testing the above suggestions, but practical considerations, unfortunately, rule out any likelihood that the X-ray analyst will be able to determine any kind of symmetry in such complicated compounds in the present generation. In Astbury's recent investigation of tartaric acid the symmetry had, perforce, to be assumed.

The only other possibility that has occurred to me is that the arrangement of the internal electrons (as opposed to the chemical electrons) may affect crystal symmetry ; but as it is difficult to see how this could have any physico-chemical manifestation at the crystal surface, it has not been further examined.

In conclusion, it will be realised that the work on sal-ammoniac may represent a turning point in the history of the X-ray method, for no matter whether X-ray symmetry be held to be a pseudo-symmetry or a true symmetry, the practical consequences are the same. As emphasised by Wyckoff, the X-ray analyst must henceforth look upon crystal symmetry with suspicion, and not be led astray at the outset of his interpretation. Unfortunately, this leaves him in the air so far as symmetry is concerned, and implies a revision of many past models. The symmetry of calcite, for example, from the X-ray point of view is not necessarily the symmetry of Haüy. To the crystallographer it will remain so, until such time as new evidence shall demand a lower symmetry.

The following summary may be useful. Each crystal has a definite symmetry—that of a structure of a physico-chemical order of complexity. At the present time the only way to determine this symmetry is to study the surface or make use of such a generalisation as the Pasteur principle, which has established itself on a permanent foundation. Any higher symmetries are pseudo-symmetries, and have their origin in a suppression of certain determinants. A notable example is X-ray symmetry, for it is compulsorily based on an atomic conception of crystal structure, and not on the molecular basis demanded by a wealth of chemical facts. An attempt is made to bridge the gulf between X-ray symmetry and crystal symmetry, but it is felt that the real solution is not yet in sight, owing mainly to the lack of a general chemical method of investigating crystal structure *in situ*.

Some Curious Numerical Relations.

IN the course of a series of computations it was noticed that the ratio of the numerical values of the following pairs of quantities is in each case an integral power of ten. This curious relation is so surprisingly exact that it seems worthy of record :

$$(h/2\pi)^2 = 1\cdot08806 \times 10^{-54} \text{ erg}^2 \text{ sec.}^2$$
$$e^3/K_0 = 1\cdot08804 \times 10^{-28} \text{ erg cm. es.}$$

$$e = 4\cdot774 \times 10^{-10} \text{ es.}$$
$$h/k = 4\cdot777 \times 10^{-11} \text{ sec. deg.}$$

$$m_0 = 8\cdot9991 \times 10^{-28} \text{ gm.}$$
$$c^2 = 8\cdot9916 \times 10^{20} \text{ cm.}^2 \text{ sec.}^{-2}$$

$$r_1 = 5\cdot30507 \times 10^{-9} \text{ cm.}$$
$$e/m_0 = 5\cdot30500 \times 10^{17} \text{ es. gm.}^{-1}$$

The symbol *es* has been used to denote the electrostatic unit of charge, r_1 the radius of the first Bohr ring in hydrogen, K_0 the dielectric constant of a vacuum, k the gas constant per molecule; the other symbols have their usual significance. The values that served as the basis of the computation were those just given for e, e/m_0, and c, and the following: h, $6\cdot554 \times 10^{-27}$ erg sec.; the faraday, $2\cdot89365 \times 10^{14}$ es. per equivalent; the volume of one gram-molecule of ideal gas at 0° C. and one standard atmosphere, 22411·5 cm.^{3} per mole; and 0° C., 273·1° K.

Lichens and their Action on the Glass and Leadings of Church Windows.

I HAVE read with great interest the paper by Dr. Ethel Mellor in NATURE of August 25 and I should like to refer to one or two points.

The paper gives the general impression that the decay of ancient stained glass is produced by the action of lichens. This has frequently been suggested, but surely the reverse is the case—the decay of the

glass is not due to the presence of lichens but the undoubted growth of lichens on it is due to, and subsequent to, the glass being decayed.

The immediate cause of decay and the formation of the characteristic pit holes is surely due to chemical and physical decomposition, and it is only when the glass is in an advanced state of decay that the lichens find in the disintegrated glass accumulated in the pits a soil suitable for their growth. (For details I would refer to an article in Nature of May 2, 1907.)

One finds, in fact, that the degree and character of the corrosion is determined by the chemical composition of the glass. The statement that the glass of the twelfth to the fifteenth century shows a slower rate of alteration than that used later needs some modification. The glass of the twelfth century was of good quality and shows little decay, but there was steady deterioration from the thirteenth to the beginning of the fifteenth century; the glass of this latter period shows the most pronounced decay. After this time the composition of the glass in general steadily improved.

The point I would particularly challenge, however, is the suggestion that windows should be treated with a liquid mastic to prevent the growth of lichens. I am not quite sure if this is intended to apply to new or old windows. If the latter, surely the remedy is a thousand times worse than the disease. If the former, I suggest that the proper way to prevent the growth of lichens is to prevent the decay of the glass which enables them to gain a foothold. That can be done only by ensuring that glass of a composition which ensures durability is used in new windows. As a matter of fact the glass used nowadays as a rule leaves little to be desired in this respect.

One further point occurs to me. I have made many analyses of medieval stained glass and I invariably find phosphates as a constituent—particularly in glass of the fourteenth century. As the glass decays this would presumably be deposited as calcium phosphate in the corrosion pits. Would this encourage the subsequent growth of lichens and account in some measure for the prolific flora described by Dr. Mellor?

Noël Heaton.

81 Queen Victoria Street, E.C.4,
August 29.

The article referred to by Mr. Noël Heaton describes the results of "one of several possible lines of research"; it shows that lichens accelerate the chemical change of the glass and lead, and exert a mechanical action on the altered glass.

Certain species of lichen are found only on unaltered glass; they do not persist, and on disappearing leave a roughened surface conformable to their own shape. On deeply corroded glass, lichen débris, not the plant, is the more frequent. Lichen physiology is a controversial subject, but the probability is that neither the calcium phosphate nor the "soil" mentioned by Mr. Heaton accounts for the flora.

References to the presence of three species of lichen on the windows of two churches are made by Fries and Nylander, and reproduced by a few lichenologues; there has been, to my knowledge, no scientific investigation of the lichen flora on church windows or of its relation to the deterioration of glass until three years ago when the research was undertaken at the Sorbonne. I cannot therefore appreciate Mr. Heaton's statement that it "has frequently been suggested" that "the decay of ancient stained glass is produced by the action of lichens." I am, however, open to correction if Mr. Heaton will give the authority for his statement.

The only modification I can make with regard to the glass of the twelfth to the fifteenth centuries is that certain glass of the twelfth century is immune, but is this not to some extent true of the glass of each century? It is reassuring to be told that "the glass used nowadays as a rule leaves little to be desired" as regards durability, when one knows that certain stained glass of so recent a date as the second half of the nineteenth century shows an advanced state of corrosion. In this case lichens have apparently played no part.

The quality of the glass is undoubtedly a factor of great importance in ensuring its durability, but it cannot prevent the growth of lichens, as some of these plants find a suitable substratum on the smooth unaltered surface of the glass. The application of a liquid mastic to exclude the lichen spores is intended for those windows difficult of access for cleaning purposes. What can be the objection to its use on old glass and not on new? The suggestion is not my own; it finds favour with one who has more than forty years' experience in the art of stained glass, medieval and modern, and has the keenest appreciation of æsthetic value.

It may be mentioned that the destructive effect of lichens on their substratum is remarkably evident on the marble statues at Versailles,—some eighteen months ago it was decided to arrest the corrosion by cleaning the marble and then treating it with a mastic.

Does Mr. Heaton use the word "disease" in its popular or pathological sense? It is to my mind as wrongly used in connexion with the corroded glass as it would be if applied to the weathering and disintegration of rocks.

Through the courtesy of Mr. J. A. Knowles, of York, I have had access to Mr. Knowles's own work and once more read Mr. Noël Heaton's papers on the composition and decay of glass. I see no inconsistency between these papers and my article in Nature of August 25.

Painted Pebbles from the North-East Coast of Scotland.

The statement that Azilian painted pebbles do not occur further north than Basle was made by me in a review appearing in Nature, August 25, p. 276. It has been challenged and the so-called painted pebbles found by Sir F. Tress Barry on the N.E. coast of Scotland recalled. These interesting objects cannot, however, be referred to the Azilian culture, and this for two reasons, namely:

(1) They were found in connexion with and in the precincts of Broch buildings, admittedly from their archæological and faunal content of much later date. It has been suggested that the Broch had been constructed on an older Azilian settlement, but this idea is vetoed by,

(2) When the actual objects are seen and handled it is found they in no respect resemble the Azilian painted pebbles. Prof. H. Breuil, of Paris—previously a partisan of the early age for these objects—at once rejected the Azilian date on seeing the specimens. I may add that I also came to the same conclusion when I saw and handled the stones.

However, it need not be added that the above in no way detracts from the interest of these queer objects from the Broch, and the problem of their meaning and object still remains unsolved.

M. C. B.

Science and Progress in Australia.[1]

By Sir DAVID ORME MASSON, K.B.E., F.R.S., Professor of Chemistry, University of Melbourne.

AN underlying motive of all international conferences is to contribute something towards that mutual understanding—that sympathy—which alone can preserve the peace of nations; but each has also its own specific work to do. The task of the Pan-Pacific Science Congress is to discuss those scientific problems which are of special interest in the Pacific area, to direct attention to them and to lay plans for future research. It is hoped that all the participating countries may benefit; but I think there are two good reasons why Australia may look to profit most. In the first place it is here that the Congress meets and here, therefore, that its deliberations will attract most attention from the public and those higher authorities that have it in their power to aid or discourage any co-operative ventures for the public good. In the second place, Australia, in respect to scientific effort, has more to learn from the older and greater nations—from the Mother Country, from America, from Japan, from Holland—than they have to learn from her.

This island continent is as large as the United States but has a population only about one-twentieth as great. It is a continent of huge distances and vast empty spaces, held by a people of nearly pure British stock, who would not run two persons to the square mile if evenly distributed over its surface. Collected on and near its coastal fringe, they have done much to open up the resources of the land and have learnt much about its difficulties. To carry on the work towards complete development, overcoming obstacles and gradually increasing the area of settlement, is the proud ambition voiced in the nation's motto "Advance Australia." Progress, full utilisation of the great land we occupy, is a duty we owe to ourselves; but clearly our obligation is even more binding as trustees for the world, present and future.

Many things are needed to ensure successful progress —the triumphant fulfilment of Australia's destiny. Statesmanship of course; but as to that we may have faith and confidence. Man-power—a vast increase of population; and towards that end even now the efforts of our rulers here and in Britain are turned, utilising and directing hither the migration wave from an overcrowded land where food is scarce: a movement which has arisen since the War and recalls the greater hunger migrations that went to make history when the world was young. But apart from these there is a need as pressing, as fundamental, though I think it is not so generally recognised of the people. That is the need of science.

Science is nothing more nor less than the knowledge and understanding of Nature's laws. To a law of Nature there can be no exception. The apparently abnormal is seen to be normal when the laws at work are better understood. There is no happening in the Universe except in conformity with natural law. No human act can successfully run counter to it. Any such attempt is foredoomed to failure. Man cannot "fight Nature"; he can but utilise its law-governed processes, profiting by the result. There is, indeed, no true distinction between what we call "artificial" (man-made) and "natural" (Nature-made). An artificial ruby is either not a ruby at all, and therefore misnamed, or it is the outcome of Nature's edict that certain substances, raised to a certain temperature, will fuse, and, on cooling, will crystallise in a certain manner. All that the artificer has done is to gather the right materials and to adjust the environment to the necessary temperatures; and, for this last purpose, he has but utilised Nature's infallible laws of chemical combination and of energy. His ruby is, in truth, as much a natural product as those man finds ready-made in the earth. Let me cite a more important case. Sir Ernest Rutherford is commonly said to have *caused* the *artificial* disintegration of certain of the lighter atoms, such as those of nitrogen, and their partial transmutation into hydrogen atoms. He is said to have done this by bombarding them with swiftly moving alpha-particles emitted by radio-active material. The facts are true, but the common mode of stating them is misleading. Not Rutherford, but Nature, did the work; not Rutherford, but Nature, caused the result. Neither the work nor the result was new. What Rutherford did was to arrange the environment so as to render detection of the phenomena possible; then to observe and then to interpret Nature's deeds. Radium and other radio-active matter have been shooting out swift-moving alpha-particles, and these have been bombarding other atoms and causing occasional transmutations, since time was young; only we did not know of it until recently. Rutherford's discovery is one of the most important events in the history of science, and none but a man with genius such as his for searching Nature's secrets could have made it. We owe to him many other discoveries of first-rate importance and surpassing interest; but even he can do no more than study Nature, follow out her processes, and elucidate her laws.

In more obviously utilitarian fields the same story must be told. The sheep-breeder who gradually and patiently improves the quality or the quantity of his wool and thus raises the value of his flock is not the main agent in the process. He merely acts as Nature's henchman and her immutable laws of heredity do the rest. So it is with the cultivator of improved varieties of wheat—rust-resisting or what not—or of varieties of beet that provide a greatly enhanced yield of sugar.

Is all this a mere truism? I think not; for there are many signs that mankind at large does not yet realise that everything that happens in this universe is the result of the working of natural laws and that the best that man can do is to study them and turn the knowledge of them to his profit. One is tempted here to ask the old question: how many utterly futile man-made laws have been passed by parliaments, foredoomed to become dead letters or to be rescinded, because they tried to run counter to the complex and incompletely understood natural laws of economics or social science?

But, if the principle I have enunciated be a truism,

[1] From the presidential address delivered to the Second Pan-Pacific Science Congress at Melbourne on August 13.

so much the better; for so much the more readily will it be conceded that a nation's progress is dependent on its *understanding* of Nature's laws. This is science; and so much more readily will Australia realise that science is as essential as statesmanship and man-power if she is to achieve greatness.

Science, of course, is too vast a study for any but those who give their lives to it to make much headway, and even these rarely can specialise in more than one of its many branches. Nature, it is true, is one and indivisible, but her work is infinite. The more we learn of her the more we realise her unity, but the more we are forced for our own sakes to subdivide and classify science. The most learned in any branch are at best but amateurs in any other. A nation, therefore, needing science, must make liberal provision for the highest training in all its branches, and must, moreover, see to it that the resulting skill and knowledge are fully utilised for the public good.

Nature being infinite, it stands to reason that what man already knows of her—the science of to-day—is but a fraction of what man may come to know—the science of the future. Yet this small fraction is in itself stupendous. In modern times, since man learnt how best to seek new knowledge, all the great nations of the earth have contributed, and as science grew its rate of growth became accelerated. Now not a day passes without additions to every branch. Scientific education, then, must be equipped to deal adequately with all this accumulated mass of knowledge; but the universities, if equipped to do no more, will fail in their task of training competent men of science to serve their country's needs, and that country will fail in its duty to the world—the duty of contributing by research to the growth of natural knowledge. The science of to-day cannot be divorced from the science of to-morrow; the power to make new knowledge is both the final test and the reward of a scientific education.

The familiar distinction between "pure research" and "applied research" is justified in this—that, while there is no real difference in the methods employed and one may require as much skill and knowledge as the other, the aims from first to last are essentially different. The aim of any pure research is nothing more nor less than to add something new to natural knowledge in a chosen field. The investigator's reward is the joy of discovery. The aim of any applied research is to solve a particular problem, the successful solution of which promises results of direct utility to man and is therefore of marketable value. It may be that the investigator himself does not reap this tangible reward; it may even be that he is content to let it go to others; but in any case his task is that of the treasure-seeker. If he find that the expected treasure does not lie where he hoped to find it, he may follow up any other likely clue to its whereabouts, but may not turn aside tempted by mere glimpses of an unknown land. It is true that exploration there might possibly lead to valuable discoveries, but that is mere conjecture: his immediate task is to unearth the treasure he went out to seek.

Such definitely utilitarian research should require but little advocacy, for it should appeal strongly, even to the unscientific. Any one can understand something of the valuable results that would follow from the discovery of a new and successful treatment of a disease rife among men or flocks and herds, of a method of eradicating a vegetable pest or a parasite destructive of cultivated crops, of an improved process of ore treatment or of metallurgical work, or of the utilisation of some waste product of a manufacture. But not everybody can realise that all such discoveries have their foundation in pure research, that the successful quest of the obviously useful is merely the last stage of an intricate series of scientific investigations, to which many workers have contributed—mostly working with the sole object of adding something to natural knowledge. Those acquainted with the history of scientific discovery and invention know that this is true. They know, moreover, that no genuine new knowledge can properly be stigmatised as useless or "merely academic," however remote from utility it may at first appear; for, sooner or later, it will be found as an essential link in the chain of truths that leads to a valuable conclusion.

When, in 1895, Sir William Ramsay separated small quantities of a gas from the rare mineral cleveite and identified its spectrum with that of Lockyer and Frankland's constituent of the sun's atmosphere, helium, the discovery was full of academic interest but certainly did not promise to be useful. On the purely scientific side the expectations have been far more than realised, for this helium element, since its discovery in terrestrial matter, has been linked up with all that earlier and later knowledge that has culminated in the proof of the electrical constitution of material atoms, or the fundamental identity of matter and electricity—probably the most far-reaching scientific advance within our memory. But, on the utilitarian side, what could offer less promise of practical application than a gaseous element, not only scarce and costly but also absolutely inert and incapable of forming chemical compounds? Yet it was this very inactivity that soon found for it an important use and market value. For, next to hydrogen, helium is by far the lightest of all gases; and, being inert and therefore totally incombustible, it is a safe gas with which to inflate balloons and airships, while hydrogen emphatically is not. The scarcity of supply was overcome when research showed it to be present in small proportions in several natural gas springs in America, and methods were devised for separating it from its companion gases in a pure state. In parenthesis it may be said that the solution of this problem of its separation, were we to follow it out in detail, would itself be seen to have been rendered possible by a chain of earlier pure researches on the physics of the gaseous state. When war ended in 1918, large quantities of pure helium, compressed in drums, were ready in America for shipment to Europe, to be used in war balloons and air-ships. This was but twenty-three years after Ramsay's "academic" discovery of the apparently useless element in terrestrial minerals and half a century after the first observation of it as a line in the spectrum of the sun's chromosphere. The armistice came too soon for it to play its destined part in war; but the ideal inflater of lighter-than-air vessels still meets a want in times of peace, and helium is now being prepared and stored in quantity in the United States, where I understand the use of any other gas for this purpose is prohibited by law.

Such examples of the complete dependence of practical science on pure research, and of the utter falseness of the idea that any genuine contribution to natural knowledge can be inherently and permanently devoid of utility, could be multiplied indefinitely. Any nation, therefore, which aims at progress must for its own sake foster to the utmost of its ability scientific education and both pure and applied research. If further reason and, perhaps, a higher reason be wanted, no civilised nation stands alone: each owes a duty to the others to do its share in the work that is essential for the world's intellectual and material—aye, and moral—progress—the making of new knowledge of Nature's eternal truths. Nothing but extreme poverty or youthful irresponsibility could excuse a nation which, shirking this sacred duty, elected selfishly to profit only by foreign-made science; and nothing is more certain than that it would profit not at all, for it would fail through sheer inability to understand.

That, of course, is far from being the case with Australia. Young though our nation is, it is not so very poor and it certainly is not irresponsible. To make progress for itself and for the world is Australia's just ambition, and it has done much already to prove that it does partly recognise the importance and the power of science. Each State has its University, and each University seeks, within its somewhat narrow means, to excel on its science side. We have our Royal Societies and others of more specialised type, our more popular Australasian Association for the Advancement of Science, and, of more recent birth but, we hope, with a great future before it, the Australian National Research Council, with important international connexions. Each State Government maintains its own scientific activities, particularly in connexion with agriculture and mining. The Government of the Commonwealth does much for public health and for meteorology; and quite recently it has undertaken to build, equip, and maintain a Solar Physics Observatory—a very important contribution to international research. Our Governments, indeed, both Federal and State, have given many proofs that they appreciate the value of international co-operation in scientific work. But democratic governments can never go very far ahead of public opinion; and our Australian people have given no sign as yet of a general understanding of what science can do for them or of an urgent desire to put it to the test.

Here, as elsewhere, there was some war-time awakening to the potency of applied research. It resulted, in 1915, in the adoption by the Commonwealth Government of an ambitious scheme for the formation of an Institute of Science and Industry, with a statutory constitution and with ample means for carrying out investigations over the wide field of Australia's primary and secondary industries. Pending the passing of the necessary Act of Parliament, the scheme was nursed for some four years by a body of voluntary workers, who tried to make up in enthusiasm what they lacked in financial means to success. That Institute now has its statutory constitution, its powers, its director and its office staff, but it has never yet been given the promised means to build the laboratories or appoint the skilled investigators essential to its proper work. War-time awakening was but temporary. It happens that I have a personal knowledge of the history of that adventure and of the difficulties put in its way by unlooked-for opposition and growing indifference in Parliament and elsewhere. That experience has convinced me that the Australian public is still largely blind to its own interests and its duty. Time and education will bring improvement. All that has yet been done is but a beginning, holding out hope of greater achievement in the future. For real progress, Australia needs a great deal more science, even as she needs more men and women.

Let me cite briefly a few of those typical scientific problems of a practical kind which have interested the Commonwealth Institute. Few of them are peculiar to Australia. Most have their counterpart in other countries, and there is none in which we cannot benefit from the experience of one or more of the countries in the Pacific area.

The settlement of people on the land, the spread of pastoral industry and of agriculture, are seriously hampered by the aggressive character of many vegetable pests of foreign origin. One of these, the prickly pear, is estimated to be now in occupation of some 24 million acres of Australian soil, mainly in Queensland, and to be spreading at the rate of one million acres a year. Australia, indeed, owns a much larger area under prickly pear than its total area under cultivation; and there are parts of Queensland so densely covered with this pest that surveys wanted for a railway extension scheme could not be carried through it. Destruction by mechanical means or by poisons has been found too costly for general use; but the biological method of attack holds out more hope. This is based on the fact that the prickly pear, as well as other pests, has been introduced without those natural enemies, insect or fungoid, which keep it in check in its native haunts. By importing them we might eventually re-establish the balance of Nature. Obviously, no such action can be taken without proof that it is free from risk to crops or pasture; and this means prolonged research by experts. Some definite progress has already been made in this direction, but much more work is wanted.

The cattle industry is beset by many ailments, which in the aggregate cost Australia millions of pounds per annum. The cattle tick, with the related tick-fever, is responsible for untold damage, direct and indirect. Similarly, in sheep country the blowfly pest causes enormous loss, especially in some seasons. All these and many other ills are, or should be, curable; and real success with any one of them would recoup Australia for all it is likely to spend on science; but nothing can be hoped for without extensive and systematically organised research.

In quite another field large progress has already been made, which, however, should but serve as a stimulus to further work. I refer to the increase of our harvests and the extension of the area available for cultivation by the selection and breeding of new varieties of plants better adapted to local conditions. Agricultural experts tell us that an increase of one bushel per acre in the average yield of wheat would represent a gain of 2,200,000*l.*, while any considerable extension of the wheat belt in average breadth by

the introduction of more drought-resistant varieties would enormously increase the nation's wealth.

Our forests, so uniquely Australian, offer problems which cry loudly for systematic scientific work, far too little attention having been paid to some of them in the past. The admirable pioneer labours of von Mueller and of Baker and Smith have opened up an almost limitless field in the investigation of the characters and the chemistry of our forest trees. Closely related is the practical problem of the development of forest-product industries. Those who have to do with the timber industry know how much remains to be done in the systematic study of the character of the timbers, their exact classification, and the methods of seasoning and of preservation. All this is apart from, though related to, the problem of forestry proper; that is, the development of a complete organisation, scientifically controlled, for the care and upkeep of the forests, which—though wantonly destroyed in the past—may still be one of the nation's great assets.

The thorough investigation of Australian clays, with the view of the development of a ceramic industry employing native material, is another example of what may be done by applied science in the future; and here again some noted advance has already been made by the Commonwealth Institute, though it has been compelled to restrict its field of work.

There are tasks ahead, however, of perhaps more fundamental importance than any of these in connexion with the development of our country's resources and the settlement of population—tasks, moreover, called for by our obligation to contribute in our own area to man's knowledge of the earth on which he lives. I refer to the need of much more extensive, detailed, and systematically organised topographical and geological surveys than any as yet provided for. Such work would seem to require a definite scheme of co-operation between the Federal and State Governments and the institution of permanent scientific services.

In Papua and still more in the Mandate Territory of New Guinea there is urgent need for systematic scientific work, both for utilitarian reasons and because the unknown, wherever it exists, cries loudly for intelligent investigation. There are not many parts of this earth's surface that remain to-day so unexplored as does much of the interior of New Guinea, or which hold out so much promise of reward to the topographer, the geologist, the chemist, the botanist, the zoologist, and the anthropologist. The services of all these are needed as regular adjuncts to the civil administration. The work should not be left to the casual efforts of individual enthusiasts or of occasional scientific expeditions, often privately financed and undertaken more in the spirit of adventure than of true research. It needs highly trained men and systematic organisation. Most pressing of all is the need of skilled ethnological work—the study of the natives, their beliefs, thoughts, languages, customs, and mode of life, while yet it is possible; for it can be but a little while before they become sophisticated—I had almost said degraded—by contact with white man.

Australia has voluntarily undertaken a difficult task and a great responsibility in New Guinea and the adjacent islands. Its position there is that of a public trustee. Surely its most urgent duty is to make full provision for the scientific study of the land itself, its inhabitants and all that it contains. How else can it hope to succeed? How else to discharge its obligation fully to mankind? Pioneering work has been done in the past by specialists, some of them leaders of the highest repute; but the time has surely come for systematic, co-operative, and government-supported effort.

There is, then, reason to hope that the public demand for science in Australia will grow—that it has a great future before it. In building up that future on the foundations already laid, the Australian people must look for guidance and example to the greater and older nations of the earth. In this, as in all things, we turn first to that Mother Country which we still call Home. There the Royal Society, pioneer among national academies of science, has taught and practised the true gospel of the pursuit of natural knowledge for 260 years, and many younger research associations have gained world-wide repute. There also the cause of applied science has gained steadily in recent times, and is now represented by a powerful Department of Scientific and Industrial Research and by such highly endowed institutions as the National Physical Laboratory. We look also to America, where the organisation and endowment of scientific work are now on a scale that arouses universal admiration, not unmixed with envy. There Federal and State authorities, great manufacturing firms and wealthy citizens, seem to vie with one another in promoting education and research, knowing that thus the greatness of their country will be yet increased. We look to Japan—that wonderland which, in so short a span of years, has made for itself in science, as in all ways, an honoured place among the great nations. We look to Holland, ancient centre of learning and of maritime discovery, famous in the history of the Pacific, and to its splendid colonies in our tropic seas; for both Motherland and colonies are known throughout the world for what they have done and are doing for science.

Science and the Agricultural Crisis.[1]

By Dr. CHARLES CROWTHER.

IT is generally recognised that the primary causes of the present difficulties of British agriculture are strictly economic in character, and not due to any gross and general failure to apply present-day scientific knowledge to the technique of farming, although the great disparity which exists between the average production of the country and that secured by the more competent farmers on soils of the most diverse natural fertility suggests that with a higher general level of technique and education the intensity of the crisis might have been sensibly reduced. Whether it be a case of the "sick devil" or not, the agricultural com-

[1] From the presidential address delivered to Section M (Agriculture) of the British Association at Liverpool on September 13.

munity is at present in a more receptive mood towards scientific advice than at any time I can recall in some twenty years' advisory experience, and I believe the moment to be opportune for a forward movement in agricultural education, which, if wisely developed, may remove the last vestiges of opposition and establish education and research firmly in their rightful places in our agricultural organisation.

Our agricultural educational system may be likened to a pyramid with research at the apex, elementary education and general advisory work at the base, with intermediate education, higher education, and higher advisory work occupying the intervening parts. Our pyramid has grown within the last thirty years from a very modest structure of low elevation into an imposing edifice, which perhaps appeals to the mind's eye more through its height than its spread, the upward growth having taken place at a proportionately greater rate than the expansion of the base. The essential need of the moment appears to be a broadening of the base with the view of greater stability and a more effective transmission of the results of the activities of the upper portions to the maximum basal area over which they can beneficially react.

For the purposes of my survey it will be convenient to follow the customary classification of our work into research, advisory work, and teaching. Of these three divisions I propose to deal but very briefly with the first, that of research, since the potentialities of research for the advancement of agriculture are too patent to require exposition, the ultimate object of all agricultural research being the acquisition of knowledge which will enable the farmer to comprehend his task more fully and to wield a more intelligent control over the varied factors which govern both crop production and animal production.

Agricultural progress must be dependent upon research, and no phase of our agricultural educational system is so full of great promise for the future as the comprehensive research organisation, covering practically every field of agricultural research, which has been brought into existence during the past twelve years, and developed upon lines which ensure an attractive career to a large number of the most capable research workers coming out of our universities. In praising the research institute scheme, I am not unmindful of the needs of the independent research worker and the spare-time research work of teaching staffs—the type of research work to which we owe so much in Great Britain—and it is with some anxiety that I have watched the distribution by the Ministry of Agriculture of the modest resources available for the support of this class of work. I trust that my fears are groundless, but I am afraid of a tendency to deflect such resources towards the work of the research institutes, a tendency which in common fairness to the independent worker should be most strenuously resisted. With a sufficiently liberal conception of the class of work which can be effectively carried through by the independent worker, there should be no difficulty in allocating these moneys to the purposes for which they are intended.

In suggesting that, in proportion to the means available, agricultural research is perhaps more adequately provided for at the moment than other branches of agricultural educational activity, nothing is further from my mind than to imply that greater resources could not be effectively absorbed in this direction. I am guided by the feeling that a due measure of proportion should be maintained between research and the organisation behind it designed to translate the findings of research into economic practice, and to secure that each advance of knowledge shall be made known quickly and effectively throughout the industry.

It is chiefly in the latter direction that agricultural science can make an immediate and effective contribution to the alleviation of the present crisis, since agricultural research in the main does not lend itself to the "speeding-up" necessary for quick action. The same applies also to formal educational work, which must necessarily exert its influence on the industry but slowly.

The one line of approach along which agricultural science can make its influence felt quickly is that of *advisory work*, which consists in the skilful application of existing knowledge to the solution of practical problems, or at most the carrying out of investigations of a simple type, with the view of securing guidance as to the solution of the problem in time for effective action to be taken.

The root difficulty of agricultural educational propaganda in the past has been to secure a sufficiently intimate and widespread contact with the farmer, and for this purpose no agency at our command is so valuable as advisory work, since it ensures a contact with the individual farmer which is both direct and sympathetic, originating, indeed, in most cases out of a direct request for help. The difficulties in the way of extending advisory work greatly I shall turn to presently, but I wish first of all to outline some of the more immediately helpful forms of advisory work which have fallen within the scope of my own personal experience.

I will deal first with soil advisory work, being actuated by the conviction that soil investigation is the most fundamental of all forms of agricultural research. Soil factors dominate the growth of crops from germination to maturity, and must influence the utilisation of the crops by the animal, which is their ultimate destiny. In stressing the importance of soil advisory work I am not unmindful of the fact that, despite the enormous volume of investigation relating to soils which has been carried out, the task of the soil adviser still remains a very difficult one, and except in a few directions, and over a comparatively small area of the country, the interpretation of soil analytical data is rarely clear. It is a sobering thought, indeed, to recall the abounding optimism with which soil analysis was entered upon some eighty years ago, and contrast the hopes then held with the realities of soil advisory work as we find them to-day.

The initial mistake—so common throughout a large part of our agricultural investigational work of the past—lay in a failure to visualise the complexity of the problem, even with due regard to then existing knowledge. The problem was approached as if the soil were to be regarded solely as a reservoir of plant food, the capabilities of which for crop production should therefore admit of complete diagnosis by

chemical analysis. The conception is fascinating in its simplicity, and has dominated the greater part of our soil work down to the present time, repeated endeavours being made by variation in the methods and intensity of the analytical attack to improve the persistently low degree of correlation between analytical data and crop results. Parallel with this at a later date was developed the mechanical conception, which found the major part of the explanation of the differentiation of fertility in the physical properties of the soil particles, while still later soil biology has asserted its claim to provide the "simple solution." The work of recent years, however, so brilliantly led in Great Britain by Sir John Russell and his colleagues, leaves us with no excuse for such restricted conceptions of soil fertility, which must now be regarded as the index of the equilibrium established by the mutual interactions of a highly complex series of factors, the variation of any one of which may affect the interplay of the whole, with consequent effect upon the rate or character of plant growth.

The problem of fertility being so complex, one might perhaps be inclined to despair of attaining anything really effective in soil advisory work, which must necessarily be dependent upon rapid and somewhat superficial examination. Such apparently is the view held by the Ministry of Agriculture, if one may judge by the conspicuous neglect of chemical and physical science in recent extensions of advisory facilities.

My own conception, however, of the present possibilities of soil advisory work is more optimistic, and, from experience covering the most diverse parts of the country, I am confident that an extension of facilities for soil advisory work would be of immediate and progressively increasing benefit to the farmer. The real difficulty at the moment is that for large tracts of the country we lack the necessary data to enable us to determine what is the "average soil" for each particular area, and until provision is made for specific soil work in these areas, which comprise the whole of the great agricultural areas of the Midlands, our advisory work relating to this raw material of crop production must of necessity remain superficial, and only too frequently ineffective.

In no direction has the need for extended soil advisory work become more evident in recent years than in the revelation of the extent to which large areas of our soils have become depleted of lime. Cases come almost daily to our notice in which this lack of lime is clearly the chemical "limiting factor," and the annual waste due to unremunerative expenditure on fertilisers on such land must indeed be very great. In many cases, fortunately, the depletion has been detected at a stage at which it is still economically remediable, but in others, unfortunately, this is no longer the case, and unless soil-survey facilities be greatly extended, it is certain that large areas of our land must steadily fall into the latter category, with the inevitable development in the near future of a problem of such magnitude as will require national action for its solution. It is worthy of note also that this problem will probably be accentuated rather than diminished as a greater proportion of our arable land reverts to grass.

A further direction in which great scope remains for the work of the soil adviser is in the economic manuring of crops. Inadequate and improper manuring is still widely prevalent, and the annual wastage of resources thereby incurred must represent a very large sum. A considerable part of this wastage is due to the widespread use of proprietary compound manures, more often than not compounded without any special reference to the soils upon which they are to be used, or even without intelligent adaptation to the special needs of the crops for which they are supplied. It is not uncommon, indeed, to find mixtures of identical composition offered for the most diverse crops. In far too many cases also the prices charged are extravagantly disproportionate to the intrinsic value of the ingredients of the mixture, and in all these various ways costs of crop production are made higher than they need be.

Passing on from soil and manuring, we come to the sphere of seed and sowing problems, presenting obviously abundant scope for advisory work. The need for good and pure seed is axiomatic. Seed must not only be good, however, but it must also be of the right kind, sown under proper conditions and at the most suitable time, and the value of advisory guidance on these points has always been recognised, especially with reference to the choice between different varieties of each particular crop. The variety tests carried out on the various college farms and elsewhere have always proved helpful in this respect in so far as they serve to demonstrate the general characteristics of the different varieties. Whether they have been equally successful in measuring the cropping capacities of the different varieties is more than doubtful, owing to their restriction to single, or at most double, plots of a kind. This has been recognised in the more elaborate schemes devised for the purpose by the National Institute of Agricultural Botany, which it is to be hoped may furnish a practical scheme for more accurate quantitative field tests in the future.

Given good seed, the improvement of crop possible through seed selection is perhaps not in general so striking as that frequently obtainable by manuring, but it may nevertheless be substantial, especially with crops such as barley, where improvement of quality may have a special value. There is also a rapidly extending field for seed advisory work in connexion with the laying down of land to grass for varying periods.

During the growth of the crop, advisory work is largely restricted to the domain of diseases and insect pests, the ravages of which take incalculable toll of our crops. I believe science can make no more directly effective contribution towards the removal of at least the technical difficulties of the farmer than the elaboration of effective preventive measures against pests and diseases.

I must pass on, finally, to the utilisation of crop products as food for animals, the line of work with which my own personal interests and activities have always been most closely associated. Looking back over twenty years of advisory activity, I realise that the position of the adviser in animal nutrition is infinitely stronger to-day than when I first assumed the rôle.

With all the newer knowledge at his command, the adviser in nutrition can now approach his work with

far greater confidence, and evidence of the increasing practical value of his work is rapidly accumulating. This is particularly the case with advisory work in milk production, a branch of feeding which lends itself more readily than most to carefully regulated rationing, owing to the ease with which the amount of product can be determined. Much success has also been met with in advisory work in pig-feeding, and to a less extent in the feeding of cattle, the lower degree of success in the latter case being due not so much to an inferior capability of the adviser to help as to the difficulty of dispelling the tradition that beef production represents the supreme accomplishment of the British farmer, as to which there is nothing left for him to learn. The work already accomplished represents, however, but the very beginnings of economy in the feeding of live-stock, and wasteful feeding of both home-grown and purchased feeding-stuffs for lack of the necessary advisory guidance is still far too widely prevalent.

Such are only a few of the aspects of advisory work, which, if extended more widely, might exercise a very profound effect upon the economy of the industry. Such extension implies, however, greatly increased resources in men and money and more efficient means of bringing the advisory facilities to the notice of the farmer.

I am inclined, indeed, to think that a more efficient propaganda is perhaps the first need of the situation, for one finds in all parts of the country an astonishingly large number of farmers who are totally unaware of the existence of advisory facilities of any kind. A more extensive propaganda will be useless, however, unless accompanied by increased provision for advice, since the present resources are already more than fully taxed by the relatively moderate volume of calls for assistance that now arise. Most of our counties have, at present, only one agricultural adviser—some, indeed, have none—and yet this slender organisation represents in large measure the base of contact with the industry upon which the whole pyramid of our advisory and educational work rests. It is here where I see the most immediately profitable outlet for any further moneys that may be available for agricultural education in the near future.

I have already alluded to the chemical gaps in our specialised advisory organisation, and I might also have indicated the similar and even less comprehensible inadequacy in the provision for specialist advice in economics; but these are relatively small matters compared with the paucity of the less highly specialised but scientifically trained advisers of the county organiser type, whose business it should be to secure the confidence of the individual farmer by personal contact, and to render him assistance either directly in the simpler problems or, in more complex cases, with the help of the specialist staff standing behind the county staff, whereby a more widespread and real appreciation of the practical value of agricultural education and research than now prevails might quickly be developed.

A great extension of advisory work, such as I suggest, must necessarily involve heavy expenditure, and further, an exceptional measure of care in the selection of men, since in the direct approach to the farmer personal qualities may in the first instance count for more than technical proficiency. Furthermore, if the full measure of success is to be achieved, it is essential that a more closely organised and intimate contact should be established between the various units of the advisory organisation, from the research station through the scientific adviser, to the practical adviser. Our present organisation is too indefinite and too widely permissive in this respect and calls urgently for consideration by all concerned, both county authorities and advisory and research workers, with the view of more effective co-ordination and co-operative effort.

I have laid great stress upon the potentialities of advisory work as a contribution to the alleviation of the present crisis, but I cannot close without some reference to the far greater contribution to the future prosperity of British agriculture which we can make through our educational system, if wisely pursued, in the training of the farmers of the future.

The existing facilities for organised agricultural education—at least so far as universities and colleges are concerned—are adequate to deal with the numbers of students presenting themselves. There is indeed at the moment a considerable excess output of the class of student who is either unwilling or unable to take up practical farming and must needs have a salaried post.

Of more immediate concern is our comparative failure to secure for our educational courses more than a small fraction of the sons of farmers, upon whom the future of the industry will largely rest. I have testified to the greatly awakened interest in agricultural education which has been displayed among farmers in recent years, but it is yet far from having developed into a conviction that such education is to be regarded as a vitally essential part of the farmer's training. One must perhaps be content with gradual advance towards this goal by internal development, although the possibilities of more rapid advance by external pressure should not be overlooked. The enlightened landowner might exert an influence more potent perhaps than any other in filling our colleges with farmers' sons, if in letting his farms — at any rate so far as young applicants are concerned—he showed his faith in agricultural education by giving preference where possible to men who have received adequate instruction in the principles of agriculture in addition to practical experience. So long as the private ownership of land continues, the landowner will have it in his power to render in this respect the most powerful aid to the progress of agricultural education, and by action along these lines might exert more good in one year than is attainable by many weary years of propaganda.

Whatever the character of our land-tenure system of the future, it is certain that sooner or later some guarantee of efficiency for the productive occupation of land will be demanded from the would-be farmer. We cannot continue indefinitely, on one hand, to proclaim that the land is our greatest national asset, to be maintained with the help of, and in the interests of the State in a highly efficient state of productivity, while, on the other hand, the use of the land is left open to all, regardless of fitness for its effective use. This vision of farming reduced to the status of medicine and law as a close profession regulated by an entrance examination, may perhaps be stigmatised as a horrible

nightmare; but some movement in that direction I believe to be inevitable, and, with nationalisation of the land, it might well come more speedily than one would venture to contemplate. None will question, at any rate, that, should such a day arrive, education in the principles underlying the calling will loom as largely as practical training in determining the standards of admission to the use of the land.

The Structure of the Great Rift Valley.

By Prof. J. W. GREGORY, F.R.S.

THE explanation that the lake chains of East Africa lie in a system of tectonic valleys which are a continuation of the basin of the Red Sea was due to Suess (1891) in his contribution to the geological results of Teleki's expedition. Suess regarded the Great Rift Valley as made by a sudden rupture of the crust of the earth owing to contraction, as preceded by no upheaval, its age as Pliocene and Pleistocene, and the height of the land beside it as due to an uplift[1] in consequence of the rupture; and he considered that as the East African Rift Valley is bounded by block mountains and not by parallel horsts, it is different in structure from that of the Rhine. The present writer, after a visit in 1892–3 to the highest part of the Rift Valley, supported Suess's view of its formation by earth-movements due to lateral tension, but he considered that the valley had a much longer and more complex history than Suess recognised; for the Rift Valley was made by faulting repeated at intervals from at least the Oligocene to the Pleistocene, it was initiated by an uplift of a broad arch in the Upper Cretaceous, and the infall of the top of that arch was probably a consequence of the foundering of the floor of the Indian Ocean.

The Great Rift Valley in its course from Syria to Mozambique varies greatly in structure. In some places it consists of a single trench, and at others of several branches. Its structure is geographically most complex in Tanganyika Territory, where it was studied with especial care when that area was part of German East Africa. A valuable discussion of the combined topographic, geological, and geodetic researches in that region has now been prepared by Prof. Krenkel, of the University of Leipzig.[2] He shows that between the Congo and the eastern coast of Africa three great tectonic belts are now well established. That nearest the coast forms the eastern front of the main African plateau. As it is the oldest, and in the most exposed position, its structures have been obscured by denudation. Hence the determination that this mountain rampart was formed by faulting required close examination of its geology. The evidence available shows that the central part of Tanganyika Territory is traversed by a zone of fractures, which extends from Lake Nyasa to the plateau front west of Mombasa. This eastern zone consists in places of a series of step faults, but includes, as in Uluguru, some rift valleys.

The second belt is the continuation of the main trunk of the Great Rift Valley southward from Kenya Colony. It includes Lake Magadi, and forks at Lake Natron; one branch goes south-westward, and includes Lake Eyasi, and disappears near the town of Tabora. The main trunk continues southward; it is repeatedly deflected south-westward by faults parallel to those of the eastern fracture belt; it becomes indefinite after passing Kilimatinde on the railway from Dar-es-Salam to Tanganyika. There is some evidence of the extension of this fracture belt through the Ruaha valley to Lake Nyasa. The only gap still uncertain in the course of the Great Rift Valley is from the lower part of the Ruaha to near Kilimatinde.

The westernmost tectonic belt follows the western branch of the Rift Valley, and includes the Albert Nyanza and Lake Tanganyika. It forks near its southern end: one branch breaks into splinters on the southern coast of Tanganyika; the longer branch goes south-eastward past Lake Rukwa, joins the main trunk at the Ruaha valley, and continues through Lake Nyasa to south of the Zambezi, where it has been traced by Teale and Wilson. The evidence of the tectonic origin of the valley is especially clear around Lake Tanganyika, the coasts of which show complex series of faults, fault blocks, and secondary rift valleys. Many of the faults are quite modern, as some of them have dislocated recent conglomerates and have tilted some of the lake beaches. The walls of this valley, from the features noted in the original graphical description of it by Burton, are young, and, as Prof. Krenkel holds, the westernmost of the three tectonic belts is probably the youngest.

Between Suess's simple theory that the Rift Valley was formed from a single series of fractures in the uppermost Kainozoic and my more complex classification with its three different series of fractures separated by four volcanic periods, Prof. Krenkel adopts an intermediate position. He accepts two periods of faulting and three of volcanic activity for the Nyasa basin; so that his sequence of events is nearly as long as mine; but he regards all the volcanic rocks as Miocene or later. The evidence on which I referred the lava of the plains near Nairobi to the Upper Cretaceous was admittedly scanty; but that age fitted in best with the general history of that part of the world. Later a promising clue to the age of the earlier volcanic eruptions was offered by Dr. Oswald's work on the Victoria Nyanza; but the volcanic pebbles he collected in the pre-Miocene conglomerates cannot be certainly identified. It is to be hoped that some visitor to that area will make a further collection of the volcanic pebbles from these conglomerates, so that their position in the East African volcanic sequence may be determined.

The view that the Kapitian lava plains are Pliocene has been held persistently; but that view has now been conclusively disproved by fossils collected by Mr. Sikes from beds deposited in depressions in the surface of these lavas. The fossils have been identified by Mr. R. B. Newton as Pliocene, so that the lavas themselves must be Miocene or older. Their Cretaceous age

[1] [In 1891 he referred to the uprise as an *Aufwölbung*; later as an *Aufwulstung*.]

[2] Die Bruchzonen Ostafrikas: Tektonik, Vulkanismus, Erdbeben und Schwereanomalien. Von Prof. E. Krenkel. Pp. viii+184. (Berlin: Gebrüder Borntraeger, 1922.) 7s. 4d.

has recently been supported by the work of E. O. Teale and W. Campbell Smith from the Zambezi. Some lavas which these authors correlate with the Kapitian are shown to be Cretaceous; they remark (*Geol. Mag.*, May 1923, p. 228), " . . . the close similarity between the specimens from the Lupata Gorge just described, and the Kapitian phonolites, seems to afford very striking confirmation of Prof. Gregory's view that the latter are of Cretaceous age."

This evidence establishes the suggested date for the beginning of the East African part of the Rift Valley by fixing the age of the oldest associated lavas as Cretaceous. That the Rift Valley faults had begun by the Oligocene has now received further confirmation from the Gulf of Suez. In a lecture to the Royal Geographical Society in 1921 (*Geog. Journ.* vol. lviii. pp. 267-271) Dr. Hume threw doubt on the fault origin of the Gulf of Suez, and attributed it to folding. This conclusion would have been difficult to reconcile with the successive maps of the area issued by the Geological Survey of Egypt had not that Survey also published a diagram of one of its folds (Petrol. Research Bull. No. 6, 1920, before p. 1). The structure represented is what in ordinary geological nomenclature is termed a fault. In answer to Dr. Hume's view that the Gulf of Suez was formed by folding, it is only necessary to refer to the two last publications on the area by the Survey of which he is director. The valuable account of the geology of the Gulf of Suez in No. 10 of the Petroleum Research Bulletins, by Messrs. Moon and Sadek, includes two sections which illustrate the structure of the Gulf. The essential parts of these sections are here reproduced (Figs. 1 and 2). They both represent the Gulf of Suez as in a typical fault-formed valley. The second figure (after Pl. IX. D) is especially instructive, as it shows that the faults which formed the Gulf of Suez were post-Eocene and pre-Miocene. It therefore shows that the conclusion that the Rift Valley faulting began in the Oligocene, which was first based on evidence from Lake Nyasa, holds for the Gulf of Suez. A further Petroleum Research Bulletin, No. 12, has just been issued, in which part of the eastern shore of the Gulf of Suez is described. The authors, Messrs. Moon and Sadek, conclude that the position of the shore is determined by " a very important fault," and they show that the faults in this area were in part pre-Miocene and partly post-Miocene. One of the sections, Pl. I. D-H, shows a series of vertical and steeply inclined fracture planes which are marked as faults and not as folds.

Suess's view that the Great Rift Valley is tectonic in origin has been supported by an overwhelming balance of opinion; but his view that it was a sudden rupture due to the contraction of the crust has been less widely adopted than the writer's hypothesis that it was due to a series of infalls along an upraised belt. That preliminary uplift has been accepted under various names —arch, anticline, or mountain ridge along the axis of the valley—and it is consistent with the gravity survey by Kohlschütter, of the results of which an excellent summary is given by Prof. Krenkel. Tanganyika Territory is under three different conditions. Along the coast gravity is in excess. The central area, along the south-western branch from the Great Rift Valley through Lake Eyasi to Tabora, includes a broad basin, with gravity less than the normal. Along the western branch of the Rift Valley is a long narrow band in which the gravity is also less than normal; Krenkel describes it as a *Dichterinne* or density-trough.

The majority of recent authors have adopted the view that the Great Rift Valley was due to lateral tension. That the faults which bound the valley might be due to compression has been several times suggested. The occurrence of reverse faults in the older rocks beside the Great Rift Valley appeared to support this possibility. This view was suggested by Uhlig in 1907, but he has abandoned it. An overthrust fault—which has since been rejected—was described from German East Africa, but Suess remarked that he knew of no other anywhere along the Great Rift Valley system. Dr. Hume inserted a reversed fault on the western shore of the Gulf of Suez. His section was reissued last year " slightly altered " (Petroleum Research Bulletin, Geological Survey Egypt, No. 10, Pl. VIII. Fig. 2); but the only noticeable modification, except in colouring, is that the fault is no longer drawn as a reverse fault.

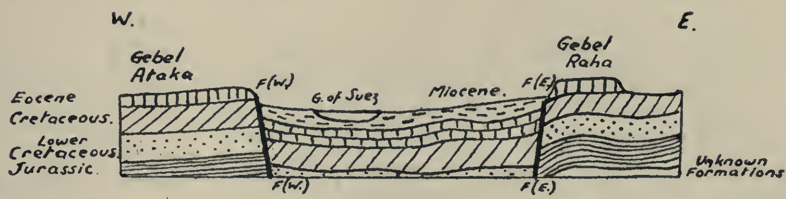

FIG. 1.—The structure of the Rift Valley of the Gulf of Suez according to the Egyptian Survey. From Petroleum Research Bull. No. 10. (Cairo, 1921.)

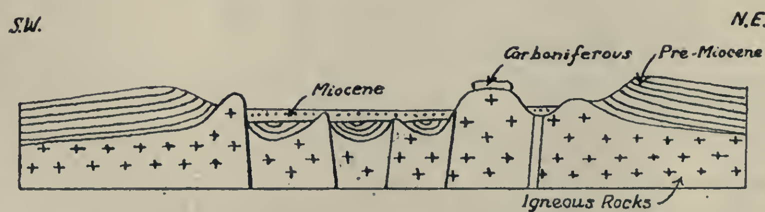

FIG. 2.—Another section by the Egyptian Survey of the valley of the Gulf of Suez. From Petroleum Research Bull. No. 10. (Cairo, 1921.)

The main advocate of the compression theory is Mr. E. J. Wayland, the director of the Geological Survey of Uganda, for the Great Rift Valley near the Albert Nyanza (*Geog. Journ.* vol. lviii., 1921, pp. 344-359). The suggestion is more probable for that area than for those places where the Rift Valley is associated with immense lava fields, and in Unyoro it has some abnormal features. Mr. Wayland's view is based on general considerations, and he does not appear to have seen any reversed fault along the Rift Valley. All the numerous faults that have been recognised in the Great Rift Valley series are normal. Any reversed faulting that may be found will probably prove to be

exceptional. The geographical and geological features of the mountains beside the Great Rift Valley resemble those of normally faulted block-mountains, and not those of fold mountains due to corrugation of the crust by compression. The topography along the Great Rift Valley agrees with that of areas torn by tension clefts rather than with mountains raised by compression; for all the faults known are normal; beside the valley rise many block-mountains and horsts, and it is associated with vast lava fields. In mountains due to compression, on the other hand, the faulting is reversed; volcanic action is rare except for isolated volcanic groups some distance from the main chain, or where it is cut across by later faults. The mountains, moreover, occur in long sinuous chains and sheaves of chains which gradually dwindle in height through parallel foothills. That the Rift Valleys are due to tension is emphatically asserted by Prof. Krenkel. The fracture zones of East Africa, he says, are zones in which the crust has been torn asunder (*Zerreissungszonen der Kruste*, p. 169).

Recent evidence, therefore, from the Zambezi and the Gulf of Suez, Mr. Sikes's fossils from the Kapiti Plains, and Prof. Krenkel's valuable monograph, combine to confirm the conclusions that the Great Rift Valley was initiated by an upbulging of the crust; that its fractures were connected with vast volcanic eruptions which began in East Africa in the late Cretaceous, and were contemporary with the Deccan Traps of India; and that one set of the fractures that made the Rift Valley happened in the Oligocene. These conclusions render it probable that the African Rift Valleys are due to the secondary consequences of the movements that made the basin of the Indian Ocean.

Obituary.

MR. F. J. H. JENKINSON, HON. D.LITT. (OXON.).

IN Mr. Francis Jenkinson, University Librarian at Cambridge, who died on September 21, has passed away one of the most versatile and distinguished of Cambridge scholars. Of his profound knowledge of classics, of bibliography and antiquarian matters, and of music, this is not the place to write. This notice must be restricted to his activities in natural science, in one branch of which, entomology, he was an expert. Nor is it possible here to give more than the briefest outline of his life. Born in 1853, he entered Marlborough at the age of twelve, and in 1872 began a distinguished career at Trinity College, remaining for the rest of his days at Cambridge. He became University Librarian in 1889, and held this post until his death, a period of more than thirty years.

Jenkinson was Curator in Zoology in the University Museum for a few months in 1878 (the same year in which he gained his Fellowship at Trinity by his classical attainments). He was the second occupant of this position, the first having been Mr. J. F. Bullar, and during his tenure he worked chiefly at insects. The same curatorship was afterwards filled (in 1890) by the late Dr. David Sharp. But though Jenkinson's official connexion with the Museum of Zoology was short, he was its valued helper to the end.

From boyhood a keen naturalist, and especially a lepidopterist, Jenkinson was much associated in early years with his lifelong friend Mr. Edward Meyrick, as a student of the smallest and most delicate forms. Some time after the coming to Cambridge of Dr. Sharp, with whom he formed a lasting friendship, Jenkinson turned his attention to Diptera. These were henceforth his special study until the last, and it is as a dipterist that he will be remembered in entomological circles.

It is true of Jenkinson's entomological side, as perhaps of all his interests, that his published works are little in comparison with the greatness of his knowledge. His writings comprise some twenty-seven short notes and papers, contributed to the *Entomologist's Monthly Magazine* between 1886 and 1922. The first four, up to 1900, deal with Lepidoptera, the remainder almost entirely with Diptera. In his longest paper (1908) he recorded a number of fungus-gnats new to Britain and described one new to science. The short notes contain records of captures and observations of the habits of various flies. His last entomological writing (1922) was an obituary notice of his old friend A. B. Farn.

But these publications are only a small part of Jenkinson's dipterological work. None could be more generous than he in aiding other workers. He had a wonderful faculty for distinguishing obscure species in the field, and very great deftness in capturing minute insects, even without a net. He was a very skilful manipulator, and collected a vast amount of material in several parts of Great Britain, but especially in his own garden at Cambridge. The pick of these captures was always at the disposal of the University Museum, to which he gave hundreds of specimens, and he was one of the makers of the Cambridge collection of British Diptera, now one of the largest extant. The national collection at South Kensington has also been enriched by many of his specimens. His miscellaneous captures in other orders were frequently interesting: a minute Copeognathe found in a house at Crowborough, and described by Dr. Enderlein in 1922 as a new genus and species (*Pteroxanium*), is the first Psocid (*sens. lat.*) with scale-covered wings to be discovered in Great Britain, the forms related to it being tropical.

Jenkinson's faculties for observing were extended to plants, birds, and even, at one time, to mollusca. He applied his classical and bibliographical knowledge also to entomological matters. The former was often called into play in questions relating to scientific names. What he wrote of Farn was true also of himself: "he disliked slovenliness" and "was the most scholarly of naturalists." As Librarian he was always sympathetic to the needs of entomology, and contributed to the result that the University Library and departmental libraries together now contain a body of entomological literature (especially periodicals) probably unsurpassed in any centre in Great Britain outside London. In person he was tall but of almost fragile build, and he was always hindered by poor health. The kindest-hearted of men, his personality exercised a singular charm over his many friends.

H. S.

Current Topics and Events.

The report of the Broadcasting Committee appointed on April 24 by Sir William Joynson-Hicks, then Postmaster-General, has now been issued, together with a statement from the present head of the Post Office, Sir Laming Worthington Evans. The committee had to consider : (*a*) Broadcasting in all its aspects ; (*b*) the contracts and licences which have been or may be granted ; (*c*) the action which should be taken upon the determination of the existing licence of the Broadcasting Company ; (*d*) uses to which broadcasting may be put ; and (*e*) the restrictions which may need to be placed upon its user or development. The Committee states that broadcasting is of value for instruction and entertainment and has great potentialities, and it is recommended that a Broadcasting Board should be established by statute to advise the Postmaster-General, though broadcasting services should remain in the hands of non-Government bodies working under Government licence. The revenue required to maintain broadcasting services is to come mainly from the receiving licence fee. The Committee considers that the existing fee of 10*s*. a year is sufficient for the present, and that three-quarters of the receipts might go to meet the costs of broadcasting. As regards licences, a uniform and simple type of licence obtainable without formalities and with practically no limitations on the apparatus is suggested for all users. Extension of broadcasting hours and of the wave-lengths in use (350-425 metres) so as to cover the range 300-500 metres, excluding the band 440-460 metres, is also recommended. The Committee considers the immediate application of its scheme desirable, and suggests that the British Broadcasting Company's licence be continued and extended on a modified basis. No recommendation is made on the subject of the protection of British apparatus against foreign competition, the Committee stating that the matter should be dealt with by Parliament.

Arising out of our recent article on "Inventors and Patents" (Nature, September 8, p. 349), it has been brought to our notice that the interest of patentees and inventors has been made the special aim of the Institute of Patentees (Incorporated). This association was founded in the year 1919, and within a short space of time enrolled some twelve hundred members. It has set up a body of technical advisers to assist the inventor and prevent him from wasting money on useless propositions. In the case, however, of those inventions which contain germs of value, even though the inventions are but crudely presented, the Institute advises their originators as to the best method of developing their productions. To a certain extent, the Institute also acts as a clearing-house, at the same time aiming at submitting to manufacturers such inventions only as have reasonable commercial prospects. In favourable cases, assistance will be given in the direction of obtaining capital for the exploitation of inventions. In order to reduce considerably the huge expense generally involved in the settlement of disputes proceeding from inventions, a Court of Arbitration has been constituted to which contentious questions may be remitted. At the present time, the Institute is concentrating its efforts on securing an Empire patent, whereby the cost of protecting an invention throughout the British Empire may be materially reduced. At the general meeting in March of this year, the chairman in his presidential address announced that the Institute was recognised by the Board of Trade, and that certain inquiries addressed to that Department were referred immediately to the Institute. It is stated that the Institute is in no way a trading or profit-making concern, for the members of its various advisory and other committees give their services gratuitously. Two classes of members are enrolled. An annual subscription of two guineas secures full membership, while associate-membership for the annual subscription of one guinea is reserved for the genuinely poor inventor. Further particulars are obtainable from the organising secretary at 44 Russell Street, London, W.C.1.

Before the War, Capt. C. W. R. Knight, as a photographer of birds and their nests, was already in the front rank. Being a practised climber, he did not confine his attention to species that build near the ground, and more recently he has specialised and taken the kinematograph as well as the ordinary camera "into the tree-tops" with most successful results. On Monday last, at the Polytechnic Hall, in Regent Street, Capt. Knight used a number of his films and some lantern slides to illustrate to a specially invited audience a lecture which will be repeated daily for the benefit of the public for several weeks to come. There is no need at the present time to emphasise the usefulness of films as records of fact (in contradistinction to portrayals of fiction) where motion has to be illustrated, or the advantage of having them verbally described. Capt. Knight was able to show the climbing of woodpeckers, the rapid flight of birds of prey when catching food for their young, the plucking of the victim, its partition among the nestlings of tender age, the throwing of it whole to them to scramble for when they were older. He also showed special records of young birds exercising their wings and getting into training for flying, as well as their hesitation before they could make up their minds to launch themselves for the first time in the air. Many points of incidental interest were mentioned by the lecturer. The finding of a swift in the nest of a hobby was used as an argument in favour of the latter bird being the swiftest of our hawks. Stress was laid upon the amount of vegetable food eaten by the greater spotted woodpecker ; the writer has known of this bird taking coconut intended for tits, but Capt. Knight described the extraction of kernels from hazel-nuts fixed in the crevices of bark, after the fashion of the nuthatch. Owls were dealt with, as was the daily life of a rookery, while the rearing of young herons was considered in detail. All who are interested in British wild life should go

to Capt. Knight's lecture, for they will thus add to their knowledge besides gaining a great deal of enjoyment.

ACCORDING to the latest estimates (given in the *Times* for September 28 and 29), the loss of property in Tokyo and Yokohama due to the earthquake of September 1 is somewhat less than was at first supposed. In Yokohama, about three-fourths of the houses (including those of greatest value) were destroyed; those which remain are apparently but a fringe of small dwellings. It was on the flat levels, intersected by canals, in which the business and shopping quarters were situated, that the destruction was greatest; but on the Bluff, where the foreign merchants lived, there was also much damage done, many of the houses having fallen into the valley below. In Tokyo, out of about 335,000 houses destroyed, only 11 per cent. collapsed under the earthquake shock; the remainder were burned. It was again in the densely crowded riverside districts that the worst of the destruction took place. It has been suggested that Yokohama should be rebuilt in a safer district, but the site of the city is obviously determined by the harbour, which has not been materially damaged. Moreover, though there is no absolutely safe area in such a seismic zone, the safest for many years to come, and perhaps for several centuries, may be the epicentral area of the recent shock.

WE are glad to note that British firms are adopting more and more the principle, on the lines of many American firms, of helping their clients in every possible way—and indirectly the general public as well—by the issue of thoroughly scientific literature written by experts. A good example of this is a recent publication, "Water Treatment," by Messrs. Brunner, Mond and Co., Ltd., the well-known chemical manufacturers of Northwich, Cheshire. This booklet, which is a production of the firm's research staff, and may be obtained free of charge by writing to the above address, gives a most lucid and concise explanation of the whole principles underlying the hardness and treatment of water, especially for boiler feed purposes, and should prove invaluable to engineers and all others in charge of boiler plant. It is divided into fourteen sections, and particularly good are those devoted to the cause of hardness, the soda ash and lime treatment, and the choice and method of operation of softening plant in general. Also of great interest are the sections dealing with the more difficult aspects of water treatment, about which the average chemist is none too clearly informed, such as the presence of free carbon dioxide and sodium bicarbonate, acids, whether mineral or of the peaty acid variety, oil, and especially the removal of the last traces of magnesium, for which the use of alumino-ferric is recommended.

IN 1905 the Meteorological Office was able for the first time to make some provision for the regular investigation of the upper air over the British Isles. Investigation had previously been carried out privately, in some cases with the assistance of the British Association and of the Royal Meteorological Society. Mr. W. H. Dines, who had taken a leading part in the practical development of the investigation, agreed to supervise the work for a nominal fee and to provide, free of charge, the facilities which his residence afforded for work with kites and balloons. After 1913 Mr. Dines removed to Benson in Oxfordshire, and for the past ten years he has continued there the upper-air work which he had carried out so successfully at Pyrton Hill on the Chilterns and at Oxshott in Surrey. Largely as a result of these investigations, England has gained a position in the forefront of the investigation of the upper atmosphere. At the end of June 1922, Mr. Dines retired from active supervision of the work, although he continued generously to give facilities for investigation to be carried on at Benson. Mr. Dines's experience indicated that open country north-west of Oxford was the most suitable place for a permanent observatory, but financial reasons made this impossible; it was accordingly arranged to utilise Kew Observatory, where the disadvantage of position would be to some extent compensated by proximity to the central office and contact with other branches of meteorological work. The transfer will probably be made in a few days. The Observatory at Benson will then be closed. The regular daily reports in connexion with forecasting will be made at the wireless station at Leafield by the courtesy of the Postmaster-General, while the upper-air investigation will be continued at Kew Observatory.

GREAT activity continues to prevail on the question of the cause and incidence of cancer. The Ministry of Health has recently issued a circular (No. 426) in which the views of a committee of experts are set forth. The circular deals with the characteristic features and natural course of the disease, the extent of cancer mortality and its increase, the proclivity to cancer, chronic irritation as a determining factor in the appearance of the disease, and the diagnosis and the treatment of cancer. The statements made are in harmony with the results of modern scientific inquiry, and the circular should help to counteract a great deal of irrelevant matter which the public has been invited to accept from quacks, cranks and well-meaning persons who do not possess the requisite knowledge. Local health authorities are encouraged to deal with the cancer problem in the best interests of the community.

Die Naturwissenschaften for August 31 contains two articles by Arrhenius and by Freundlich on the life and work of Wilhelm Ostwald, who reached the age of seventy on September 2, as recorded in our issue of August 25, p. 289.

A REVIEW of the adhesives industries appears in the *Chemical Trade Journal* for September 14. The properties, composition, extraction, and sterilisation of animal glues are concisely described. Vegetable glues (*e.g.* from starch), waterproof glues, and various forms of adhesives (*e.g.* sodium silicate adhesives, adhesives from cellulose waste, liquid glues, etc.) are all treated. A solution of glue in acetic acid is the basis of "seccotine."

A review of the dye-stuffs industry of Great Britain, by Prof. G. T. Morgan, is published in *Chemistry and Industry* for September 14. In this the progress made during and since the War in the manufacture of intermediates and dyes is discussed in great detail, and the article gives a reasoned account of the present position and future prospects of one of the most important British industrial undertakings.

The autumn conference of the Textile Institute will be held at Leicester on October 18-19. The first day of the meeting will be spent at the Exhibition of Textile Machinery and Textile Fabrics which is being held in Leicester on October 10-20. On the second day, Mr. P. E. King, of the University of Leeds, will present a paper on "Artificial Silks," and later the annual Mather lecture will be delivered by Prof. J. F. Thorpe, who will take as his subject "The Application of Dyes to Fibres and Fabrics." The remainder of the meeting will be devoted to visits to works in the neighbourhood of interest to members of the conference.

The first paper-mill for producing printing paper and pasteboard from hydrophytes or water-plants on a large scale was started on September 15 in Grossenhain, Saxony. The hydrophytes (Typha, Phragmites, etc.) are made into pulp by a cheap new process of the German Hydrophyte Co., and are said to yield a good material for paper and pasteboard. The reeds grow wild in shallow waters and their removal is desirable in the interests of fishing; in Germany, therefore, as in other countries, large amounts of the raw material are to be had freely. It has been calculated that in Germany alone one million tons of dry reed material can be gathered, thus freeing for other purposes a like quantity of wood up to now used for manufacturing wood pulp and cellulose. Several further works for producing paper pulp from reeds are to be erected in Germany as well as in other countries. It is stated that the same process may also be used for bamboo and similar tropical plants.

The Gilbert White Fellowship offers an attractive programme for the present session ending January 1924. Meetings and expeditions have been arranged for most Saturdays during the winter; noteworthy events are lectures by Dame Helen Gwynne-Vaughan on "The Mechanism of Inheritance" on November 3 and by Mr. F. R. S. Balfour on "Trees and Flowers of the North-West Pacific Coast" on December 1. The Ramble Section of the Selborne Society has also issued a programme of its fixtures for the next few months (price 6d.). Numerous "rambles" of historic and literary interest are included, mostly in London and its museums. Lectures have been arranged apart from the rambles and among them are "Among the Himalayas," by Mr. F. W. Hodgkinson, on October 31; "Japan, Past, Present and Future," by Prof. Wilden-Hart, on November 7; "In Neptune's Kingdom," by Mr. F. Martin Duncan, on November 14; "Animal Disguises and Camouflage," by Mr. Wilfred Mark Webb, on November 29; and "Nature at Home," by Mr. M. A. Phillips, on December 12. Correspondence relating to the rambles, other than applications for tickets, should be sent to Mr. P. J. Ashton, 72 High Street, Bromley, Kent.

A special volume of the *Zeitschrift für Kristallographie*, comprising no less than 640 pages and numerous illustrations and plates, has been published as a testimonial to the magnificent life-work in crystallography of the founder and first editor (for over fifty volumes) of the *Zeitschrift*—Prof. P. von Groth. It consists of contributory memoirs on their most recent original researches by thirty-two authors of repute, mostly well-known contributors to the *Zeitschrift* for many years and old friends of Prof. von Groth. The two British contributors are Dr. Tutton and Mr. Barlow, the former of whom sends a thirty-five-page paper on the completion of his many years' work on the sulphates, selenates, and double salts, in the results of which Prof. von Groth had taken a very deep interest, while the latter sends a paper on the division of space in enantiomorphous polyhedra. The universal character of this remarkable birthday present—for it commemorates the eightieth birthday of Prof. von Groth, which occurred on June 23—will be apparent from the mere mention of the names of a few of the contributors from other lands. First should be mentioned Prof. Niggli of Zurich, who now acts as editor and to whom the greatest credit is due for the organisation of such a memorable testimonial to the great crystallographer; then we have memoirs from Prof. Jaeger of Groningen, M. H. Ungemach of Paris, A. Hadding of Lund, C. Leiss of Berlin, J. Beckenkamp of Würzburg, G. Aminoff of Stockholm, F. Zambonini of Turin, H. Tertsch of Vienna, F. Rinne of Leipzig, C. Viola of Parma, E. Artini of Milan, R. Scharizer of Graz, and others equally famous from almost all the greatest European centres of learning. The value of these papers alone is a noteworthy testimony to the great esteem and affection in which the recipient is held, and their publication as a common dedication at a time like the present should prove a valuable aid to international peace and goodwill. The volume is dedicated to one of the greatest of modern men of science, one of the kindliest of men, who ever gave the impulse of his encouragement and approbation to those striving sincerely and earnestly to advance the subject which he had so much at heart.

Messrs. Longmans and Co. have many science books in their new list of announcements. Among them are "The Action of Alcohol on Man," by Prof. E. H. Starling, with contributions on alcohol as a medicine, by Dr. R. Hutchison; alcohol and its relations to problems in mental disorders, by Sir Frederick W. Mott, and alcohol and mortality, by Prof. Raymond Pearl; and "Galvanomagnetic and Thermomagnetic Effects: The Hall and Allied Phenomena," by Prof. L. L. Campbell (in Monographs on Physics).

The autumn announcement list of Messrs. Methuen and Co., Ltd., contains many books of scientific interest. Among them we notice "The Principle of Relativity," by Profs. A. Einstein, H. A. Lorentz,

H. Minkowski, A. Sommerfeld, and H. Weyl, translated by Drs. G. B. Jeffery and W. Perrett, consisting of a selection of the more important scientific papers in which the theory of relativity was originally expounded; a new and revised edition of "The Foundations of Einstein's Theory of Gravitation," by Prof. E. Freundlich, translated by H. L. Brose; "Einstein's Theory of Relativity," by Prof. Max Born, translated by H. L. Brose (the book aims at giving a lucid historical account of Einstein's Theory of Relativity); "The Chemical Elements," by F. H. Loring, dealing with recent developments in connexion with the chemical elements along lines which include electron binding processes in atomic structure, in radiation phenomena, and in electromagnetic reactions (the quantum theory and the stationary states of the Bohr atom are illustrated by analogy); "Radioactivity," by Prof. K. Fajans, translated by T. S. Wheeler and W. G. King; "Crystals and the Fine-Structure of Matter," by Prof. F. Rinne, translated by W. S. Stiles (the book presents a comprehensive survey of the fine-structure of matter as elucidated by the study of crystals); "Practical Mathematical Analysis," by Prof. H. von Sanden, translated by Dr. H. Levy; "The Mechanism and Physiology of Sex Determination," by Prof. R. Goldschmidt, translated by Prof. W. J. Dakin, presenting in concise form a review of the most modern knowledge of the mechanism and physiology of sex determination, and in particular of the theories of Goldschmidt; a translation, by J. G. A. Skerl, of Prof. A. Wegener's "The Origin of Continents and Oceans"; "What is Man?" by Prof. J. A. Thomson; and "The Origin of Magic and Religion," by W. J. Perry, describing briefly the growth and spread of religion and magic.

Our Astronomical Column.

FIREBALL OF SEPTEMBER 7.—Mr. W. F. Denning writes: "About 35 descriptions of this object, which appeared about 7 h. 45 m. G.M.T., were received from Cornwall, Devonshire, and South Wales. It was of considerable size and brilliancy, and it left a trail which remained visible for 10 or 12 minutes, according to several of the observers. A number of the reports which have been received are not of any scientific utility, for they are mere descriptions of the brightness of the phenomenon without including any precise details of the position of the flight and duration. Some of the observations, however, contain all the data necessary for computing the real path of the meteor.

"The radiant point is indicated at 260°–12°, and the height from about 69 to 26 miles descending along a course 100 miles in length, at a velocity of 20 miles per second. It extended from south-west of Land's End to about 25 miles west of Lundy Island, and it lit up brilliantly the sea and coast of Cornwall in the district nearly over which the meteor descended."

PROF. LINDEMANN'S THEORY OF THE SPIRAL NEBULÆ.—The *Observatory* for September contains two articles criticising this theory, which suggested that the spirals were clouds of cosmic dust, expelled from the galaxy by light-pressure, and shining by reflected starlight. Prof. Perrine considers the idea of their shining by reflected light untenable, on the ground that at least one of them, N.G.C. 1068, has some bright lines in its spectrum, which show the same radial velocity as the dark ones; in case of reflection the latter would be double the former. Mr. A. C. Gifford notes that the presence of layers of dark obstructing matter in many of the spirals negatives the idea of reflected light from the galaxy, a point which was also made by Mr. Reynolds.

Prof. Perrine agrees with the suggestion of expulsion from the galaxy, but holds that the spirals are no longer merely dust clouds, but that a large number of stars have formed in them by condensation; they are autonomous systems, perhaps 100 light-years in diameter; the novæ in them are supposed to be similar to, but perhaps smaller than, galactic novæ; they may be caused by stars colliding with streams of cosmic dust.

Mr. Gifford notes that Lick Observatory photographs show that the number of spirals approaches a million; assuming with Lindemann that each has a mass of ten thousand suns, we obtain an aggregate mass greater than we can reasonably suppose to have been expelled from the galaxy, since it exceeds many estimates of the united mass of the galactic stars. He agrees with Perrine in supposing that the spirals contain many condensed stars, and ascribes the novæ observed to collisions of star with star.

SOLDNER AND THE GRAVITATIONAL SHIFT OF LIGHT.—Prof. T. J. J. See and others have lately asserted that J. Soldner had anticipated Einstein in 1801 in announcing the double shift of light-rays passing near the sun. R. Trumpler examines the matter in Pub. Ast. Soc. Pacific for August, and shows, as might be expected, that the double value arises solely from an arithmetical blunder of Soldner's, who was of course using the Newtonian Law. Soldner's aim was to find the deflexion due not to the sun, but to the earth. Curiously enough, a second arithmetical blunder caused his result to be ten times too great, *i.e.* 0·001″ instead of 0·0001″; both values are far too small for practical measurement.

The charge of plagiarism against Einstein is thus shown to be completely unfounded. Cavendish had investigated the shift at about the same time as Soldner, but did not get the erroneous double value. They both assumed the corpuscular theory of light. The idea that the shift was to be expected on the wave theory came much later.

STAR-GAUGES AT LUND OBSERVATORY.—Nos. 30 and 31 of the Lund Meddelanden contain some useful work on star-gauging. The first is a rearrangement of the gauges of Sir William and Sir John Herschel. They are reduced to galactic longitude and latitude, and expressed as star density per square degree in each region measured. References are also given to the sheets of the Franklin Adams chart containing the region; the greatest and least numbers per square degree are 9630 and 20.

No. 31 contains details of the star-counts made at Lund on the Franklin Adams charts. Separate figures are given for each magnitude down to the 15th and for different distances from the centre of the plate. The density per square degree in each zone is also given. It will be remembered that Chapman and Melotte published a similar study of these plates in the memoirs of the R.A.S. However, as there is room for personality in the estimates of magnitude, an independent count is quite useful. At present there is no general discussion of the results of the count, but this will doubtless follow; in the meantime the work is very serviceable for reference.

Research Items.

THE ORIGIN OF AMERICAN QUILL-WORK.—The methods of American quill-work are figured and described in the August issue of *Man* by Mr. H. Ling Roth. Mr. Ling Roth remarks that the principle of capping the quill ends over a band of weft, twined-work, or sinew, distinguishes the technique of American quill-work from that of other peoples—Tyrolese or Nepalese—who practise quill decoration. But, strange to say, the same method is used by Ainu mat-makers, and bearing in mind the ethnic connexion between north-east Asia and north-west America, he suggests that the American technique was brought from Asia, and that Americans in later times, finding that the soft porcupine tail-quills were adaptable for this form of decoration, made use of the comparatively new-found material, and gave us the much-admired quill-work ornamentation, an invention in itself of no mean order.

THE WINNEBAGO AMERICAN INDIANS.—The chief contribution to the thirty-seventh annual report of the Bureau of American Ethnology, 1915–16, published in the present year, is a monograph on the Winnebago tribe by Mr. Paul Radin. The Winnebago and closely related tribes, like the Missouri, Oto, and Iowa, certainly represent the second westward migration of the Siouan tribes. It is impossible to say when they entered Wisconsin, but if they can be identified with the builders of the effigy mounds, they came from the south or south-east. But it is remarkable, if this theory be accepted, that no effigy mounds are found in Illinois, and it may be assumed that the Winnebago developed the mound-building habit after they had reached Wisconsin; or that other types of mounds in Illinois are the work of them and kindred tribes. It is also possible that since the effigy mounds are undoubtedly associated with the clan organisation, this type of social organisation was adopted by the Winnebago only after they had entered Wisconsin. This well-illustrated monograph gives an elaborate account of the history, archæology, material culture, social customs, clan organisation, and the cults of the Winnebago.

THE THRESHER SHARK.—In *Science* of July 13 Prof. W. E. Allen gave a description of the behaviour of a thresher shark (*Alopias vulpes*), as observed by him on the coast of California. We have received from Prof. Allen another account of the same occurrence. The shark was seen in pursuit of a small fish, which it overtook, and then, turning sharply downwards and to the right, made a whip-like stroke with its long tail, almost instantly followed by another stroke; as a result the victim was badly crippled and would have been an easy prey, had the shark not been frightened off. Prof. Allen concludes that the long whip-like tail of Alopias is a highly efficient weapon for crippling its prey, and he contrasts the methods of this shark with those used by the soupfin shark (*Galeus zygopterus*), which chases a fish with its mouth directed towards the fugitive, trying to snap it up when close enough to so so.

THE PERIODICITY AND MIGRATIONS OF LOCUSTS.—In the *Bulletin of Entomological Research* for July, Mr. B. P. Uvarov discusses the habits of the swarming locust, *Schistocerca gregaria* (*peregrina*), which is the only Old World representative of the genus. The locust *Acridium flaviventre*, Burm., is regarded as no longer a distinct species but as the solitary phase of the dimorphic species *S. gregaria*. Mr. Uvarov agrees with the conclusion of Vosseler that the migration of *S. gregaria* either as nymphs or adults has nothing to do with need for food or with the search for new breeding-grounds, and a solution of the phenomenon is not yet forthcoming. Künckel d'Herculais has observed, and Vosseler has studied more thoroughly, the extremely interesting colour changes in the individuals forming migratory swarms. These changes in *S. gregaria* are very pronounced, and Mr. Uvarov believes that they are in direct physiological connexion with the maturation of the sexual products, and of the development and reduction of the fat-body. The life-cycle of this species is very poorly known and its permanent breeding-grounds and the conditions under which breeding takes place are greatly in need of study. The author's conclusion regarding two different phases of the species suggests a promising line of investigation. Opportunities should be taken during years of mass invasions to observe the conditions of existence of the migratory phase, and also during years of minimum prevalence, when the solitary phase is most likely to be met with. Observations of this kind recorded by Morstatt in East Africa suggest that the periodicity of locusts is not due to invasions from outside, but to increased local multiplication under dry conditions.

SURVEYS IN NORTH-WEST YUNNAN.—In the *Geographical Journal* for September there is published a map of part of North-West Yunnan which has been corrected by Mr. E. A. Reeves from the observations of Prof. J. W. Gregory and Mr. C. J. Gregory, Mr. Kingdon Ward, and Mr. E. C. Young. This map shows that part of the Salween River between about lat. 27° 30′ N. and lat. 26° 30′ N. is entirely unmapped. Most of the longitudes depend upon traverses and not on astronomical determinations. The altitudes along Prof. Gregory's route are based on a series of boiling-point observations.

DISTRIBUTION OF LAND AND SEA IN PAST TIMES IN AUSTRALASIA.—Now that the hypothesis of drifting continents has added a new fascination to palæogeography, geologists will find the series of maps and considerations put forward by Prof. W. N. Benson, of the University of Otago, New Zealand, of permanent value for consultation ("Palæozoic and Mesozoic Seas in Australasia," Trans. New Zealand Institute, vol. 54, p. 1, 1923). The paper is a highly interesting "attempt to trace the geographical evolution of Australasia," and the author concludes that the opening of the Cainozoic era saw Australasia broken into blocks, the various regions thenceforth having individual and not connected histories. These regions provide the geographical features traceable at the present day. Prof. Benson takes us from the Tēthys belt to the Antarctic fringe, and he even includes (pp. 46 and 48) such a detail as the evidence of glaciation on the borders of Western Australia and South Australia at the close of Cretaceous times.

THE LAVAS OF THE PACIFIC BASIN.—Dr. H. S. Washington has traced the sequence of three types of basic lavas in Hawaii in the past, and the irregular outpouring of all of these types at the present day, from the collation of a large series of analyses, mostly due to his own work, and forming a very solid contribution to petrography (*Amer. Journ. Sci.*, vol. 206, p. 465, June 1923, and vol. 207, p. 100, August 1923). It may be remembered that this indefatigable author ("The Deccan Traps and other Plateau Basalts," Bull. Geol. Soc. America, vol. 33, p. 803) has recently concluded that the marked fluidity

of basalts forming widely spread flows depends on their high iron-content, and not on temperature or water. They show, indeed, little explosive tendency. Judd and Cole (Quart. Journ. Geol. Soc., vol. 39, p. 457. 1883), discussing the prevalence of glassy products in Hawaii, laid stress on the temperature-factor; but recent experiments in the Kilauea crater do not indicate anything abnormal in this respect. Washington's analyses, like those of Cohen, show that the Hawaiian lavas are olivine-basalts and basaltic andesites, without any unusual iron-content that might render them more fluid than the materials that have given rise to plateaux elsewhere. The remarkable prevalence of basaltic glass among the Pacific lavas remains unexplained.

Cainozoic Mammalia in American Museums.—The mounting of fossil mammalian skeletons, from material that is often marvellously complete, has become a fine art in the United States, and W. D. Matthews' paper, "Fossil Bones in the Rock," in the admirably illustrated journal *Natural History* (vol. 23, 1923; American Museum of Natural History) describes the process in a specific example. We learn how the blocks of stone are removed from the quarry, how the bones are cleaned from the alluvium of the swamp that proved a grave for their first owners, and how a reconstruction is made on one side of the mounted skeleton to represent the animal in its habit as it lived. The author deals with the three forms that abound, to the exclusion of other and even neighbouring mammals, in a quarry in Early Miocene strata near Agate, Sioux County, Nebraska, where they were first discovered in 1877. The species are *Diceratherium cooki*, a dwarf par-horned rhinoceros a little larger than a pig (see also Nature, vol. 110, p. 585, 1922); *Moropus elatus*, a clawed ungulate, combining characters of the horse, the rhinoceros, the tapir, and the titanothere, and as large as a modern camel; and *Dinohyus hollandi*, the giant pig, which is the largest known entelodont, and was presumably of savage disposition. Mr. Matthews suggests that some common drinking-habit brought these three animals into association; but may we not picture the formation of an *enclave* by three communities at some attractive spot, like those indicated by C. B. Moffatt and other naturalists in the case of wild birds on coastal flats? The museum picture (p. 368) of the association is delightful. M. R. Thorpe (*Amer. Journ. Sci.*, vol. 207, p. 91, August 1923) treats of new restorations in the Yale Peabody Museum, and illustrates *Merycoidodon gracilis*, one of the oreodont ungulates, walking delicately; its larger relative, *M. cuthbertsonii*, grazing copiously; and the carnivore *Daphænus vetus*, thin-flanked and prowling. The specimens are from the Middle Oligocene White River beds of the prolific Sioux County, Nebraska. In the following number of the *Journal*, p. 229, the same author describes the progress of our knowledge of the Merycoidodontidæ from Leidy's work in 1848 onwards, and points out a number of primitive and also carnivore-like characters in the group.

Upper Air Results in Japan.—The Journal of the Meteorological Society of Japan for January contains a communication on the summary of pilot-balloon observations at Tokorozawa by Mr. Sekine. The observations were carried out at the aerodrome of the Military Aviation School at Tokorozawa, situate in 35° 48′ N. Lat. and 130° 28′ E. Long. from observations with a single theodolite and with 40 gm. balloons, from January 1921 to September 1922. The results of 81 trustworthy ascents were used to obtain the average wind velocity and the wind directions. The observations confirm the prevalence of the great westerlies at heights above 1500 m. According to the author's opinion the height of the monsoon in this region is limited to 1500 m., above which the return current prevails to 4000 m., while above this, again, the anti-trade is said to have a slight northerly component.

Resistance Glassware.—There has recently been added to the list of resistance glassware another make produced by the well-known firm of Messrs. Chance Bros. and Co., Ltd. This new British laboratory glass forms the subject of a pamphlet received from the firm stating the result of tests made on its chemical and thermal resistance at the National Physical Laboratory. Four reagents were employed to test the resistance to chemical attack, namely, steam and water at four atmospheres pressure, boiling and evaporating hydrochloric acid of specific gravity 1·15, boiling 2N-caustic soda and a mixture of 2N-ammonium chloride and (1 to 3 of water) ammonium hydroxide. The second and fourth of these reagents produced no action that could be detected. Comparative tests using another make of British resistance glass showed the new glass as distinctly its superior in resisting the action of water and steam and hydrochloric acid while it was inferior in respect to the caustic soda test, although even here it had the advantage of remaining unclouded after attack. Flasks of the new glass, filled with molten paraffin wax and plunged into water at 15° did not crack until temperatures between 210° and 240° C. were reached, being much superior to the glass selected for comparison. On these results, the new glass quite worthily takes a position among the resistance glasses of the first rank.

Radio Direction Finding by Reception.—The Department of Scientific and Industrial Research has published the first of a series of special reports dealing with the work of the Radio Research Board. The report, which is made by R. L. Smith Rose and R. H. Barfield, gives a discussion of the practical systems of direction-finding by reception. They divide the various systems of radio-telegraphic direction-finding into three distinct groups which they call the single frame coil, the Bellini-Tosi, and the Robinson systems. They first give the history of direction finders and then a simple approximate theory. They demonstrate that in all general particulars the underlying principle of the three systems is the same. It has to be remembered that a tilted wave front does not produce directional errors. A very large number of experiments were made on damped and undamped waves to find the relative merits of the three systems. The variations from the true directions given by the methods were found to be in close agreement. At night time the direction for the minimum value was not sharply defined, and so large observational errors sometimes occurred at night. The experimental results show that all existing systems give results which are practically identical with a single twin loop rotating about a vertical axis. Whatever distortion is produced in an arriving electromagnetic wave by the geographical surroundings, and whatever the cause of the variations experienced both by day and night, all the systems were affected to the same degree. An advantage claimed for the Robinson set is that it can be used in a noisy room. No experiments, however, have yet been made to determine the relative merits of the systems in this respect.

The Liverpool Meeting of the British Association.

THE meeting of the British Association which concluded on September 19 was in many ways notable, and marked the successful introduction of various changes in the local and scientific proceedings. In point of numbers it was the third largest meeting (Australia in 1914 excepted) in the long history of the Association, but the actual number of tickets taken is not the only criterion for success. Figures are, however, of some value; for one of the objects of the Association, namely, to spread knowledge of science and what it stands for, can be most successfully accomplished by an appeal to the public receiving ready response.

While the membership numbered 3296, not less than 15,000 people attended the free public lectures in Liverpool and the surrounding boroughs, while more than 7000 paid admission to the Scientific Exhibition held under the auspices of the Association in the Central Technical School on September 10-22, and this number does not include members of the Association itself, who were admitted free.

Further, the sectional meetings were almost all not merely well attended but often overcrowded, a condition which spoke well for the enthusiasm for scientific knowledge among the members, but also illustrated the attractiveness of the programmes.

The inaugural meeting, when the president delivered his address, was remarkable for the fact that the whole proceedings were broadcasted, and in two halls in Liverpool the wireless version was accompanied by lantern illustrations identical with and shown simultaneously with the originals shown during the address itself in the Philharmonic Hall. The address was well heard in most parts of the British Isles, and was even picked up so far away as Switzerland. This is, indeed, an example of the development of physical science since the last Liverpool meeting held in 1896.

The place of the customary second evening lecture was taken by a most successful scientific soirée given by the Local Committee at the University. A wonderful series of experimental and other exhibits had been arranged and a most comprehensive programme had been prepared, but unfortunately, owing to the awkward lay-out of the University Buildings, it must have been nearly impossible for very many of the large and enthusiastic gathering to see properly one-half of all the interesting things on view or to hear many of the excellent series of lecturettes. Such a soirée, however, is full of value and was greatly appreciated, and the excellence of all the arrangements at it reflected the greatest credit on all those concerned in its organisation.

A delightful reception was given by the Lord Mayor and Lady Mayoress in the splendid suite of buildings comprised by the Walker Art Gallery, Picton Reading Room, Hornby Library, and the Museum, which for the purpose were all thrown *en suite*. Seldom if ever have these rooms been seen to better advantage, and the arrangements for dealing with such a large gathering left nothing to be desired.

Important points in the work of the various Sections will be dealt with in special articles, but, as already mentioned, sectional activity was more pronounced than at any recent meetings.

In the physical and chemical sciences this was no doubt partially due to the presence of a remarkably large number of the most brilliant workers in these fields. With Sir Ernest Rutherford as president of the Association, Prof. McLennan as president of Section A, and Prof. Donnan of Section B, and the presence of Sir William Bragg, Sir Oliver Lodge, Profs. Bohr, Langevin, G. N. Lewis, Coster, Hevesy, and a host of other well-known names, these Sections could scarcely fail to be of unusual importance and interest. Indeed, Sections A and B represented an extraordinarily representative gathering of the great men of all countries. Other sections were equally happy in the importance of the subjects they presented, and possibly to the lay mind proved an even greater attraction than the recent developments of atomic theory and the electrical constitution of matter.

It was most satisfactory to find the true scientific interest of the meeting as undiminished as in pre-War years, and this Liverpool meeting a worthy successor to the very successful one of a quarter of a century ago.

The fifty-five general and sectional excursions arranged this year were all well patronised, the number of applications for many exceeding the possible number for the excursion. As practically all the excursions at this meeting had a more or less definite scientific interest as distinct from mere picnics, it is clear that members are as keen to follow science afield as in the lecture room.

At the close of the meeting a party went for four days on a visit to the Isle of Man. Granted good weather they should have seen all that is most interesting in the Island to archæologists, geologists, botanists, and marine biologists.

In conclusion a word must be said about the Reception Room. Few cities possess a hall at once so commodious, convenient, or beautiful as St. George's Hall. The fine tessellated floor (unknown to most even of Liverpool citizens, since it has not been on view for nearly twenty years) was greatly admired, and with the comfortable furnishing and floral decorations made a charming central meeting-place for members. The Reception Room was rarely empty, and helped in no small measure the success of the meeting by forming a convenient and comfortable rendezvous.

The Liverpool Meeting of 1923 will certainly be handed down as one of the really successful meetings of recent years.

ALFRED HOLT.

The International Meteorological Conference at Utrecht.

SINCE the first steps were taken in 1853 towards international co-operation in meteorology, the International Meteorological Organisation has had a varied career, its meetings sometimes taking the form of congresses of plenipotentiaries appointed by Governments and convened through diplomatic channels, and sometimes of conferences of directors of meteorological services and observatories meeting without official aid.

Until 1919 the Organisation had no written constitution, but at the first Conference held after the War, at Paris in 1919, "Règlement de l'organisation météorologique internationale" was formally adopted. According to these rules the International Meteorological Organisation comprises: (1) Conferences of Directors; (2) the International Meteorological Committee; (3) Commissions. The Conferences are to meet every six years and to consist of "all heads of Réseaux of stations in each country and the Directors of Meteorological Observatories which are official and independent of one another," to whom are added a number of directors of private institutes and representatives of Meteorological Societies.

The International Meteorological Committee is

appointed by each Conference to act until the meeting of the next Conference, and is to all intents and purposes the executive body of the Conference, for it carries out the decisions of the past Conference and prepares the business of the next. Each member of the Committee must belong to a separate country and must be the director of an independent meteorological establishment. Commissions are appointed by the Committee "to advance the study of special questions," and members are appointed simply from the point of view of their personal qualifications to assist the work of the Commission. In this way the assistance of men of science and private gentlemen unassociated with official services is made available and freely used.

When the Conference met in Paris in 1919 the political state of the world was so abnormal that invitations could not be sent to some countries, and many other countries were not able to be represented. It was therefore felt that another Conference should be called as soon as conditions became more favourable and all countries without exception could meet in council. When the International Meteorological Committee met in London in 1921 it was considered that such a time was rapidly approaching, and the invitation of Prof. van Everdingen, director of the De Bilt Observatory, Holland, for a meeting of the Conference in Utrecht during 1923 was accepted. The return to normal political relationship has not been so rapid as was expected, and the troubles of the early months of 1923 made it look at one time as if the Conference would have to be postponed, but it was finally decided not to cancel the invitations which had been despatched in December 1922, and this course has been justified by the successful meetings of the Conference held in Utrecht on September 7–14.

The meetings of the Conference were preceded and followed by meetings of several Commissions. The Commissions for Agricultural Meteorology, Solar Radiation, Terrestrial Magnetism and Atmospheric Electricity, Weather Telegraphy and Maritime Meteorology were held before the Conference (September 3–6), and the Commission for the Study of Clouds and the Commission for the Upper Air met after the Conference (September 14). For the meetings of the Commissions and Conference fifty members were present from Argentine (1), Austria (1), Belgium (2), Brazil (1), Denmark (1), Spain (2), Finland (1), France (5), Great Britain (5), India (1), Japan (4), Norway (3), Holland (11), Poland (2), Portugal (1), Russia (2), Sweden (3), Switzerland (2), Czecho-Slovakia (2).

At the first meeting of the Conference on Friday, September 7, Sir Napier Shaw (Great Britain) was elected president, and Dr. Hesselberg (Norway) secretary-general. After the president's address had been delivered and certain business matters disposed of, it was decided to remit all reports and resolutions submitted to the Conference to five sub-commissions for preliminary consideration and the preparation of suitable recommendations. This distribution occupied the greater part of the meeting on Friday afternoon, when the Conference adjourned until the following Tuesday to give the commissions time to prepare their reports. When the Conference reassembled on Tuesday it worked very hard for three days considering the sixty odd resolutions submitted for its approval.

The great development of the use of wireless telegraphy in the dissemination of meteorological data has necessitated very intricate co-operation between meteorological services all over the world, especially in Europe. As the information is distributed broadcast for the use of any one who cares to receive it, it is highly desirable that the messages issued in the various countries should be of the same form and in the same code. As the result of untiring work of the Weather Telegraphy Commission under the guidance of its energetic president, Lieut.-Col. Gold, the New International Code is now used by twenty-two meteorological services. The arrangement of the times of issue of the wireless messages to prevent interference is also a difficult matter and necessitates close co-operation. It is not surprising, therefore, that twenty resolutions were submitted to the Conference by the Weather Telegraphy Commission. These dealt with such questions as the wording and interpretation of the code, times of issue, description of the stations, reduction of pressure to sea-level, additional observations, and the establishment of sub-commissions to watch the working of the code and to study proposals for improvements. A new departure was the agreement to add a new group of figures to certain messages, to allow experiments to be made of a new method of forecasting, based on a close study of cloud forms, which has recently been developed by the French Meteorological Office. It was very gratifying that it was not found necessary to alter the International Code, for it is extremely difficult to carry through a change when so many services are concerned, and it would jeopardise all the progress made towards the use of a uniform message if changes were made by some and not by others.

The resolutions submitted by the Commission for Maritime Meteorology were less numerous, but they contained references to several remarkable advances towards the extension of synoptic methods to ships at sea. The Commission recommended the adoption of a code to be used for wireless weather messages sent out from ships. The code consists of eight groups of figures, the first four of which are called universal groups and will be the same for all ships in all parts of the world; the second four, called national groups, will be different according to the office which organises the issue, and will be designed to meet the different needs of the various services. This proposal, which was accepted by the Conference, marks a great advance in international co-operation in all parts of the world. The Conference also recorded its appreciation of the work performed on board the *Jacques Cartier*. This is a French ship which has made experiments during voyages between America and Europe of collecting meteorological information by wireless telegraphy from ships and shore, preparing a meteorological chart of the Atlantic, and then broadcasting forecasts for the use of ships. The *Jacques Cartier* carries an officer of the mercantile marine trained in the French Meteorological Office, who is assisted by a clerk lent by that office. Further developments along these lines are to be expected.

The power of the method of "correlation" when applied to meteorological data is now generally recognised by meteorologists. The success of Dr. G. T. Walker, who employs this method in his forecasts of the Indian monsoon, is well known. Such work, however, fails unless homogeneous data extending over a long period are available. Prof. Exner, of Vienna, brought this matter before the Conference, and a resolution was adopted expressing the opinion that the publication of long and homogeneous data from a number of stations at distances of about 500 or 1000 kilometres from one another would be of great value. Not content with expressing this opinion, the Conference asked Dr. G. T. Walker to supervise the working of the resolution so far as Asia is concerned, and similarly Prof. F. M. Exner for Europe, Mr. H. H. Clayton for America,

and Dr. G. C. Simpson for Africa, Australia, and the ocean generally.

The Conference was unable to solve the problem submitted to it by the Commission for the Upper Air regarding the international publication of upper-air data. That these data should be collected and published in a uniform manner is highly desirable, but all the efforts of Sir Napier Shaw, the president of the Commission, to find a possible way of doing so have been unavailing. Such an undertaking would be expensive and would require financial aid from all countries concerned. In present circumstances it is not surprising that such aid is not forthcoming, and all the Conference could do was to make suggestions for meeting temporarily the pressing need for the rapid circulation of results obtained by means of sounding balloons. The data obtained by the use of aeroplanes and pilot balloons are too numerous to be handled internationally at present, and the Conference therefore recommended that each country should publish its own data.

Many resolutions dealing with agricultural meteorology, terrestrial magnetism, atmospheric electricity, solar radiation, and the upper atmosphere were adopted, but space does not allow of further details here.

One of the most important questions dealt with by the Conference was its relationship to the International Union of Geodesy and Geophysics. The great growth of the official weather services of all civilised countries has provided so many questions of administration and organisation for international consideration, that this side of the activities of the International Meteorological Organisation has swamped the scientific side. At recent meetings of the Conference and Committee there has been no time for scientific discussion, and therefore little to attract the members of the Organisation other than those connected with the great official meteorological services. A resolution was therefore considered to alter the rules in such a way as to limit membership of the Conference to directors of meteorological services. There was practically no opposition, and the rule governing the membership of the Conference now reads as follows :—

" The Officers of the Committee shall invite to the Conference all heads of Réseaux of stations in each country which are official (d'état) and independent of one another."

It was generally understood that this would remove from the work of the Organisation all questions of pure science, and that the science of meteorology would be considered only in so far as it is applied to the needs of the meteorological services. Practically, this is no change in the work of the Organisation, but it makes a clear distinction between the sphere of the International Union of Geodesy and Geophysics and the sphere of the International Meteorological Organisation. There should now be no material overlap between the work of the Union, which considers meteorology from the scientific side, and the work of the Organisation, which " studies only those questions which are of interest to all national meteorological services and which necessitate the utilisation of their own network of stations."

At the last meeting of the Conference, when the new International Meteorological Committee had been elected and Sir Napier Shaw was about to terminate his long connexion with international meteorology, Col. Delcambre, the head of the French Meteorological Office, rose and in a short eloquent speech expressed the regard every member of the Conference felt for Sir Napier Shaw and the debt which meteorology owed to him. He then proposed that Sir Napier should be elected an honorary member of the International Meteorological Committee, an honour never before bestowed. The proposal was accepted with prolonged applause and much feeling, for all felt that this was a happy way of marking their appreciation of the great work done by Sir Napier Shaw for international meteorology.

The newly elected Committee met the next day and appointed Prof. van Everdingen president, and Dr. Hesselberg secretary. The office of vice-president was left vacant for the present.

The general feeling at the end of the meetings, frequently expressed, was that good work had been done and much progress made. Good feeling between members from all countries was very marked throughout.

The Emerald Table.

By E. J. Holmyard.

One of the most famous of alchemical tracts is the Emerald Table (" Tabula smaragdina "), ascribed to the almost mythical " founder of chemistry," Hermes Trismegistos. Not merely is it regarded as a masterpiece by the medieval alchemists themselves, but later historians of chemistry have written innumerable articles in a vain attempt to solve its perennial mystery. The Latin text of the Tabula has been printed so many times that it is unnecessary to reproduce it here; it may be seen in Kopp's " Beitr. zur Gesch. der Chemie," p. 377, while an English translation is given by Thomson in his " History of Chemistry," p. 10.

The problems presented by the Tabula are shortly as follows : (1) In what language was it originally written ? (2) What is its age ? (3) Has it anything whatever to do with alchemy ? The third of these problems need not be discussed in this place : it is sufficient to remark that it has always been considered alchemical in nature, and in that judgment we may reasonably acquiesce.

The question of the age of the work needs a fuller treatment. It was first printed at Nuremberg in 1541, under the title " Hermetis Trismegisti Tabula smaragdina, in ejus manibus in sepulcro reperta, cum commentatione Hortulani," but according to Kircher (" Oedipus Aegyptiacus," 1653, II. ii. p. 428) it is mentioned by Albertus Magnus in his " Liber de secretis chymicis," which is, however, probably spurious. Kriegsmann (" Hermetis Trismegisti . . . Tabula smaragdina," 1657) maintained that the work was originally written in the Phœnician language, and says that, according to some, the Emerald Table was taken by a woman called Zara from the hands of the dead body of Hermes in a cave near Hebron. Other authors inform us that Alexander the Great, on one of his journeys, discovered the sepulchre of Hermes and in it the tract inscribed upon a table of emerald. These obviously legendary accounts led many historians of chemistry to doubt the great age of the Tabula, and Thomson (*op. cit.* p. 13) says that " it bears all the marks of a forgery of the fifteenth century." Kopp, however, showed that it was well known to European alchemists in the middle of the thirteenth century, and that it was mentioned by Albertus Magnus (1193–1282) in a work which is

undoubtedly authentic, namely, the "De rebus metallicis et mineralibus" (lib. 1, tract. 1, cap. 3). The commentary on the Tabula by Hortulanus, to which reference has already been made, might be used to show an even greater antiquity, if Hortulanus were safely to be identified with John Garland (1202–1252), but this identity is open to grave doubt.

The last word on the subject was that of Prof. E. O. von Lippmann, in his admirable book "Die Entstehung und Ausbreitung der Alchemie" (Berlin, 1919, p. 58): "Ein griechisches Original der 'Tabula smaragdina' ist nicht bekannt, und da die syrischen und arabischen Chemiker ihrer überhaupt keine Erwähnung tun, so bestehen berechtigte Zweifel an ihrem vorgeblichen Alter; so alt wie der gesamte zugehörige Litteraturkreis könnte sie aber dem soeben Ausgeführten zufolge immerhin sein, und die Anführung des Hermes Trismegistos, sowie die Herübernahme des im Lateinischen ganz ungebräuchlichen Wortes *telesmus* (τελεσμός) lassen eine Übersetzung aus dem Griechischen mindestens als möglich erscheinen." In short, although the earliest definite mention of the Tabula is that made by Albertus Magnus, there is a possibility that the claim of the alchemists, namely, that it was translated from the Greek, was well founded.

The following observations, therefore, would appear to be of considerable interest, as throwing further light upon both the age of the Tabula and the language in which it was written. The celebrated Jābir ibn Ḥayyān, who flourished in the last half of the eighth century A.D., wrote a very large number of books on alchemy, a partial list of which is given by Al-Nadīm in his encyclopædia, the "Kitāb al-Fihrist" (tenth century A.D.). This list was compiled partly from Jābir's own catalogue of his writings, and there seems to be no doubt of its authenticity, especially as about fifty of the books mentioned are still extant. The first book on the list is one entitled "Kitāb Usṭuqus al-Uss al-Awwal," a title which Berthelot ("La chimie au moyen âge," iii. 32) translates "Le livre d'Estaqès, le premier myrte." This mysterious translation is explained by the fact that apparently Berthelot's translator did not know the meaning of the word *Usṭuqus* and mis-read *Ās* (myrtle) for *Uss* (base or foundation). *Usṭuqus* is, I believe, an Arabic transliteration of the Greek ἑστηκώς, which is used by Aristotle in the sense of "firm" or "solid," and was extended in meaning to include the basis of anything, and thus, for example, the "four elements" as the basis of all things.

The "Kitāb Usṭuqus al-Uss al-Awwal" (al-Awwal = *the first*) is followed by a second (al-Thānī) and a third (al-Thālith), and although no MSS. of these works are known in Europe, there are, I believe, some in India, where in 1891 a lithographed edition was published. The copy I have used was kindly lent me by Mr. A. G. Ellis of the British Museum. Now, in the second book of the *Usṭuqus* (p. 41 of the lithographed edition) occurs the passage: "Balīnās mentions the engraving on the table in the hand of Hermes, which says:

'Truth! Certainty! That in which there is no doubt!

'That which is above is from that which is below, and that which is below is from that which is above, working the miracles of one [thing].

'As all things were from One.

'Its father is the Sun and its mother the Moon.

'The Earth carried it in her belly, and the Wind nourished it in her belly, as Earth which shall become Fire.

'Feed the Earth from that which is subtle, with the greatest power.

'It ascends from the earth to the heaven and becomes ruler over that which is above and that which is below.'

"And I have already explained the meaning of the whole of this in two of these books of mine."

Although the Arabic text of the Table is obviously corrupt, and the translation of it here given therefore uncertain in one or two minor points, there can be no doubt that a version in Greek was known to Jābir, since the correspondence of the above with the Latin text—the appropriate portions of which are appended—is very close:

"1. Verum sine mendacio certum et verissimum.

"2. Quod est inferius est sicut quod est superius, et quod est superius est sicut quod est inferius, ad perpetranda miracula rei unius.

"3. Et sicut omnes res fuerunt ab uno meditatione unius, sic omnes res natae fuerunt ab hac una re adaptione.

"4. Pater ejus est Sol, mater ejus Luna, portavit illud ventus in ventre suo, nutrix ejus terra est.

* * * * * *

"7. Separabis terram ab igne, subtile a spisso, suaviter magno cum ingenio.

"8. Ascendit a terra in coelum, iterumque descendit in terram, et recipit vim superiorum et inferiorum."

The Balīnās mentioned by Jābir is Apollonius of Tyana, who was born a few years before the Christian era, and acquired a great reputation in the East as a wonder-worker and as a master of the talismanic art.

It seems, therefore, that we must antedate the "Tabula smaragdina" by four hundred years at least, and probably by twelve hundred; its existence in a Greek form is rendered in the highest degree probable, and it must be acknowledged that in the Tabula we have one of the oldest alchemical fragments known.

University and Educational Intelligence.

Cambridge.—The vice-chancellor, Dr. E. C. Pearce, in the course of his address on the opening of the new academic year on October 1, said that the University Grants Committee had informed him that from the academic year now opening the Government proposes to make an additional annual grant of 30,000*l.* to meet the needs of the University for superannuation, stipends, maintenance of the Library, extension of extra-mural work, and the women's colleges; in addition a non-recurrent grant, not exceeding 35,000*l.*, will be payable in respect of superannuation arrears.

Glasgow.—Dr. J. R. Currie, professor of preventive medicine in Queen's University, Kingston, Ontario, has been elected to the newly established Henry Mechan chair of public health. Dr. Currie during the War was specialist sanitary officer at Toronto and Dunkirk, and was Medical Officer of the Scottish Board of Health 1919–1922. His work on the "Mustering of the Medical Service in Scotland," published last year, gives a stirring account of the efforts made in Scotland to keep up the supply of medical officers for the Army and Navy, and to organise the remainder for civil needs. Dr. Currie was secretary of the Emergency Medical Committee.

St. Andrews.—Dr. Adam Patrick has been chosen by the University Court to succeed Prof. Stalker in the chair of medicine, and the directors of the Royal Infirmary, Dundee, have appointed him one of their physicians. Dr. Patrick is a graduate in arts with honours in classics and M.D. with honours of the

University of Glasgow. He has been assistant successively to Prof. Samson Gemmell and Prof. T. K. Munro, of the chair of medicine at Glasgow. During the War he was working for more than three years as a specialist in bacteriology in Malta and held other appointments in the Army Medical Service.

On the nomination of the Council of the St. Andrews Institute for Clinical Research, the Court has appointed Mr. Norman Maclennan to the lectureship in bacteriology vacant through the resignation of Lt.-Col. W. F. Harvey.

DR. ROHMANN, professor of physics at the Munster University, formerly at Strasbourg, has been appointed to the newly-founded chair of mathematics and physics in the Forstlichen College, Hann.

THE Bocconi Commercial University, Milan, has resumed this year the publication, suspended since 1915, of its Annuario. Its student enrolment shows a steady increase from 65 in 1915–16 to 352 in 1919–20, followed by a decrease to 293 in 1921–22. The teaching staff comprises 31 professors and lecturers. Annexed to the University are an institute of political economy and a laboratory of technical and commercial research.

THE Faculty of Medical Sciences of the University of London, University College, announces for 1923–24 that each of the departments for the preliminary and intermediate medical sciences is equipped not only for the preliminary and intermediate courses for medical degrees but also for more advanced work. Organised courses of advanced study in experimental physiology and biochemistry are provided, and there are post-graduation courses in hygiene and public health leading to the various diplomas and qualifications in public health. A special post-graduate prospectus is being issued.

STATE policies in regard to the financing of public instruction are described and criticised by Prof. Fletcher H. Swift of the University of Minnesota in Bulletin 1922, No. 6 of the United States Bureau of Education. The growth of expenditure on the public schools since 1871 in the United States has been 900 per cent., varying from 750 in the North Atlantic and North Central States to 1400 in South Atlantic and South Central and 4000 per cent. in the Western States. The professor opines that these expenditures will continue to increase, and he recommends that the major portion of the burden be shifted from the local communities to the State. He would have the State provide the cost of teachers' salaries, supervision, general administration, and the supply of such materials as text-books and laboratory apparatus, leaving to the local communities the provision, furnishing, repairing, operating, and maintaining of school buildings, together with responsibility for fuel, water, light, power, insurance, playgrounds, and play apparatus. He estimates that the State would, under such a distribution, have to bear from 75 to 80 per cent. of the total costs. To "worshippers at the shrine of the ancient fetish of local support and local control" he says this system has led to "multitudes of children being denied educational opportunity and the herding of thousands in dismal hovels under the tutelage of wretchedly underpaid teachers, while hundreds of communities are able to provide luxurious educational facilities." One would like to know whether Prof. Swift has seen Mr. Bernard Holland's article in the *Edinburgh Review* for January, in which some of the disadvantages of centralised control of education are set forth.

Societies and Academies.

PARIS.

Academy of Sciences, September 10.—M. Emile Roux in the chair.—M. **Hadamard**: Vortices and surfaces of slipping in fluids.—Louis **de Broglie**: Waves and quanta.—MM. **Mengaud** and **Mourié**: The meteorite of Saint-Sauveur (Haute Garonne): the circumstances of its fall.

CAPE TOWN.

Royal Society of South Africa, July 18.—Dr. A. Ogg, president, in the chair.—E. **Newbery**: On a proposed modification of the cathode ray oscillograph. The modification would fit the instrument better for the study of over-voltages.—J. S. **Thomas** and R. W. **Riding**: Note on the polysulphides of ammonium, with some considerations regarding the constitution of the polysulphides of the alkali metals. The action of sulphur on solutions of ammonium hydrosulphide in dry alcohol resulted in the formation of ammonium pentasulphide only. When sodium is the metal used, the tetrasulphide is formed; with potassium the pentasulphide. Ammonium pentasulphide in alcoholic solutions is capable of dissolving still more sulphur, and there is evidence of the existence of higher polysulphides; a heptasulphide has been isolated. Pyridine and nitrobenzene react with ammonium pentasulphide, giving highly coloured solutions. There is probably in the polysulphide molecule, two sulphur atoms in a different state of combination from the remainder, and the disulphides may be regarded as being derived from a form of hydrogen disulphide represented by the formula H.S.S.H. Higher polysulphides are then formed by the addition of sulphur to the disulphides, compounds of the type $\mathrm{R.}\underset{\substack{\parallel \\ \mathrm{S}}}{\mathrm{S}}\mathrm{.S.R}$, $\mathrm{R.}\underset{\substack{\parallel \\ \mathrm{S}}}{\mathrm{S}}\mathrm{.}\underset{\substack{\parallel \\ \mathrm{S}}}{\mathrm{S}}\mathrm{.R.}$, etc., being thus obtained. This view is confirmed by the decomposition of ammonium pentasulphide into the disulphide and free sulphur. The reaction takes place at a low temperature and is quantitative in character.—M. **Rindl**: The active principle of *Homaria pallida* (Yellow Tulp). The active principle has digitalis-like physiological effects.

CALCUTTA.

Asiatic Society of Bengal, August 1.—F. C. **Fraser**: Zoological results of the Percy Sladen Trust Expedition to Yunnan, under Professor J. W. Gregory, in 1922.—Dragonflies. The collection consists of nearly 200 specimens, the majority of which belong to the sub-family Libellulinæ. The species are mostly Oriental, but a few Palæarctic forms occur from high altitudes. Twenty-three species are represented, of which seven are described as new.—B. **Prashad**: Observations on the respiration of the Ampullariidæ. After a short survey of the previous literature on the subject of the respiration of the apple snails, an account of the respiration in the common Indian *P. globosa* is given. The peculiarities noted in the case of the hill-stream form *Turbinicola saxea* are also described, and the probable causes of these peculiarities with reference to the hill-stream habitat are discussed.

Official Publications Received.

Proceedings of the Royal Society of Edinburgh, Session 1922–23. Vol. 43, Part 2, No. 8: The Theory of Alternants from 1896 to 1917. By Sir Thomas Muir. Pp. 127-148. 2*s*. Vol. 43, Part 2, No. 9: The Mechanism behind Relativity. By Dr. W. Peddie. Pp. 149-153. 9*d*. Vol. 43, Part 2, No. 11: Further Tests upon Dewar Flasks intended to hold Liquid Air. By Henry Briggs and John Mallinson. Pp. 160-169. 1*s*. Vol. 43, Part 2, No. 12: The Interior and Exterior Space-Time Forms of the Poincaré Electron in Weyl's Geometry. By John Marshall. Pp. 170-179. 1*s*.

Diary of Societies.

TUESDAY, OCTOBER 9.

INSTITUTION OF PETROLEUM TECHNOLOGISTS (at Royal Society of Arts), at 5.30.—E. H. Cunningham Craig: Recent Research bearing upon the Origin of Petroleum.

INSTITUTE OF MARINE ENGINEERS, INC., at 6.30.—W. J. N. Vanstone: The Pyramids of Egypt. (Ladies' Night.)

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—O. Brockbank: Petra, the Rosé Red City.

QUEKETT MICROSCOPICAL CLUB, at 7.30.—Dr. E. W. Bowell: The Radulæ and how to mount them.

WEDNESDAY, OCTOBER 10.

PREHISTORIC SOCIETY OF EAST ANGLIA (at Geological Society), at 2.15.—J. G. Marsden: Note on Flint Implements of Le Moustier Type from Camborne and Southampton.—Henry Bury: Some Aspects of the Hampshire Plateau Gravels (Presidental Address).—M. C. Burkitt: A Newly Discovered Transition Culture in North Spain. — A. L. Armstrong: Preliminary Report on the Discovery of a hitherto Unknown Phase of Early Mining at Grimes' Graves.—Major A. G. Wade: A Series of Ancient Flint Mines at Stoke Down, Sussex.

INSTITUTION OF WELDING ENGINEERS (at Holborn Restaurant), at 8.—Electric Welding; Gas Welding.

THURSDAY, OCTOBER 11.

INSTITUTE OF METALS (London Local Section) (at Institute of Marine Engineers), at 8.—Dr. D. Hanson: Chairman's Address.

FRIDAY, OCTOBER 12.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—C. T. Holland: The Snow and Ice Scenery of Switzerland.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—W. Y. Lewis: The Never Stop Railway.

PUBLIC LECTURES.

MONDAY, OCTOBER 8.

UNIVERSITY COLLEGE, at 5.—Prof. G. Dawes Hicks: The Philosophy of Bernard Bosanquet.—Prof. D. Jones: The Application of Phonetics to the Languages of the British Empire.

KING'S COLLEGE FOR WOMEN (Household and Social Science Department), at 5.—Prof. V. H. Mottram: Newer Aspects of Nutrition. (Succeeding Lectures on October 15, 22, 29; November 5, 12, 19, and 26.)

TUESDAY, OCTOBER 9.

KING'S COLLEGE, at 5.30. — Prof. H. Wildon Carr: The Hegelian Philosophy and the Economics of Karl Marx. (Succeeding Lectures on October 16, 23, and 30.)

UNIVERSITY COLLEGE, at 5.30.—Prof. C. Spearman: Psychology as Transfigured Behaviourism.

GRESHAM COLLEGE (Basinghall Street), at 6.—A. R. Hinks: Astronomy. (Succeeding Lectures on October 10, 11, and 12.)

WEDNESDAY, OCTOBER 10.

KING'S COLLEGE, LONDON, at 4.30.—Dr. C. Da Fano: Histology of the Nervous System. (Succeeding Lectures on October 17, 24, 31; November 7, 14, 21, and 28.)

UNIVERSITY COLLEGE, at 5.—Morris Ginsberg: The Sociological Work of the late Dr. W. H. R. Rivers;—at 7.—A. H. Barker: The Heating Equipment of a Small House.

SATURDAY, OCTOBER 13.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Capt. W. H. Date: Wireless Telephony—a Popular Exposition.

SATURDAY, OCTOBER 13, 1923.

A Representative Body for Science.

FROM time to time proposals have been made for the establishment of a body representative of British scientific opinion—professional or otherwise; and various opinions have been expressed as to the constitution and functions of a body of this kind. It seems desirable, therefore, to consider some of the questions raised by these proposals.

First it may be asked whether such a body does not exist already. A fully representative body is one which can recommend a course of action in the perfect assurance that its recommendation will be accepted by all but an insignificant minority of its constituents. There are bodies representative in this sense of some groups of scientific workers; there are others which, in the opinion of their members, should be, or some day may become, fully representative. But there does not seem to be any body which actually possesses at the present time the necessary authority over all scientific workers.

The second question is whether there is such a thing as scientific opinion, of which any body can be representative. The opinion relevant to our discussion is not that concerning technically scientific matters. Such opinion is not formed in council, and needs no enforcement, even among the laity. The only matters on which a representative scientific body could usefully express an opinion are those on which the laity judge for themselves, and are not always prepared to accept the verdict of scientific workers. For our purpose there is no scientific opinion unless there are questions on which scientific workers, while agreeing substantially among themselves, are apt to differ from important sections of the rest of the community. There probably are such questions; for example, there is the recognition, economic, political, and social, to be given to scientific work. Other matters need not be mentioned; but, since our judgment of the desirability or possibility of a representative body is likely to be greatly affected by our view of the nature of the problems with which it will have to deal, every one who discusses the matter should start by suggesting to himself concrete examples of such problems.

Supposing, then, that it is decided that there is a group of problems on which a definite scientific opinion exists, we may proceed to inquire whether it is likely that any actual representative body would succeed in expressing it. If there is any doubt on this matter, it will probably arise from a fear that any body of the kind proposed would be sure to lose touch with the average scientific worker and fall under the domination of some unrepresentative clique. The danger must be recognised, for scientific workers are often not highly

endowed with the "political sense." Methods of avoiding it will be considered later; but here it may be pointed out that an undue insistence on the danger may defeat its purpose. It is fatal to assume at the outset that the body is going to fall into the hands of a clique; many promising organisations (not necessarily in the scientific world) have failed to express the general will merely because a large section of the community, seeing among its original promoters some persons with whom they disagree, have overlooked the presence of others with whom they do agree and have refused to join it. Further, it must be remembered that, if there is not perfect unanimity, the minority is sure to accuse the majority of being dominated by a clique; it always does. Every political party, for example, when it is really in a minority, always maintains that the nation is being led astray by some small band of evilly disposed persons.

Next, if there is a scientific opinion which can be expressed by a representative body, could it be enforced? Here any discussion would probably turn on the analogy of bodies representative of other professions, such as lawyers, teachers, or doctors. The analogy suggests that the outlook is promising, but the differences as well as the resemblances should be noted. Men of science form a much less homogeneous body than any of these three professions; moreover, the laity is, or was until quite recently, much less firmly convinced of the need for the profession at all. However, this is not the objection usually raised on this score; it is sometimes suggested that a representative scientific body, though it might exercise great influence, could attain its ends only by means of some coercion on its own members or the outside public, which is intrinsically undesirable. To those who do not believe that all interference with the action of others is illegitimate it may be suggested that "coercion" is a relative term. Most people use the term only when they object to the ends to which the proposed "coercion" is directed; they seldom shrink from any form of pressure which is unavoidable if ends are to be attained in the justice of which they believe firmly. Objection on this score is usually closely associated with the fear of a dominant and hostile clique.

These simple considerations suggest others concerning the constitution of a representative body. To-day all will probably agree that its constitution must be "democratic," that its constituents must include all who have any right to be termed scientific workers (and nobody else), and that each constituent must have equal voting power in determining its policy. But that is not enough; the constituents must be real and active, and must take a constant interest in the body supposed to represent them. This result will probably not be achieved if all representation is indirect, and the selection of the council (for some kind of council is clearly necessary) lies in the hands of subsidiary bodies appointed by direct election; such indirect election will be all the less satisfactory, if those subsidiary bodies are selected primarily for some other purpose. This point is important, because one method by which a representative body might be established would be by some kind of federation of existing organisations, such as the professional institutes. While it will probably be necessary, as well as desirable, that the institutes should be given a constitutional relation to any general representative council, we doubt whether a council based solely on such bodies would remain sufficiently closely in contact with all shades of scientific opinion. A considerable proportion of the "franchise" must surely be direct; and even that part which is indirect should take into account as many and diverse classifications of the scientific community. Even in the initial stages, which lead up to the establishment of the representative body, direct expression of opinion should be encouraged. We think that no steps should be taken until the proposals have been fully discussed either at meetings or in the columns of scientific journals.

But no franchise, however perfectly designed, can secure the continual interest which is the sole guarantee of true representation. The representative body must have some work to do which will affect every constituent and make it impossible for any one to remain indifferent. This work need not necessarily concern matters on which there is likely to be general agreement, and on which it is proposed that the body shall make a pronouncement of scientific opinion to the outside world; indeed, any pronouncement which the body may make with substantial unanimity will have much greater force if it is known that on other matters of internal moment there is no sign of unanimity. The body must not seek to secure an undisturbed atmosphere of philosophic calm; it must handle controversial issues, because they alone are vitally interesting.

Here is the gravest problem; for if any controversial issue is recognised from the start as within the scope of the body, those who think they will be in a minority on that issue will try to hinder its establishment, and will undoubtedly succeed. We would, therefore, put forward a concrete suggestion. It is that, at the outset, the body should direct its attention to one problem only, namely, to the establishment of a register of qualified scientific workers. The problem will have to be solved if the body is to be called into existence; it raises difficult questions on which almost every one has some opinion; but the controversies that are likely to arise in its discussion will not necessarily be

fatal. They are not likely to be bitterly personal; for at the start all questions will concern classes and not individuals; it is sure to be recognised that individuals already existing are given the benefit of every possible doubt. Again, minorities are likely to resent exclusion rather than inclusion; the hostility of a minority whom it is proposed to exclude is clearly not so important as that of one which, by its secession, can ruin the scheme. Further, a registering body would probably have little difficulty in securing immediately some official position and recognition. These reasons seem to point clearly to registration as the first task of the representative body; but, since registration in science is not a matter of primary importance, we would make it clear that we do not think it worth while to establish a registering body unless it is understood that, when this part of its work is concluded, it is to develop wider activities.

Synthetic Colouring Matters.

Synthetic Colouring Matters: Dye-stuffs derived from Pyridine, Quinoline, Acridine and Xanthene. By Prof. J. T. Hewitt. (Monographs on Industrial Chemistry.) Pp. xi+405. (London: Longmans, Green and Co., 1922.) 14*s*. net.

IT is probable that when the monographs on colouring matters which are promised in the introductory note to Sir Edward Thorpe's series on industrial chemistry have been published, they will represent as complete a compilation of the essential facts as exist in any language. Moreover, they will probably form a convenient source from which those who wish to obtain full information on this important branch of organic chemistry can readily do so without having to spend time and energy in consulting such cumbersome literature as that of the *Fortschritte*. The first volume to appear, that on the "Natural Colouring Matters," by Perkin and Everest, is already known and appreciated by chemists, and we have now to look forward to the publication of no less than six volumes on synthetic colouring matters by authors who should know what they are writing about. The first of these volumes to appear has the title given at the head of this review, and sets a standard which augurs well for the success of the series.

Probably few books are more difficult to write (or to read) than those which deal with a highly specialised and commercialised branch of science, such as that which includes the synthetic colours. It would not be so bad if scientific literature alone had to be summarised, because in that case the author's task of discriminating between fact and fable would be reduced to a minimum. With the synthetic colours, however, much of the grain is hidden under the mass of chaff which constitutes the patent literature, and the difficulties of winnowing are great. It is difficult to understand why so much money and energy are devoted to the collation of chemical patent literature when, as most people know, much of it is untrue and a great deal of the remainder misleading. Chemical patent literature is, and always has been, and probably always will be, written by lawyers for lawyers; and it will probably always be the case, in spite of restrictive legislation, that the manufacturing firms concerned will often be inclined to place no small value on any publication which tends to mislead their competitors, and where some is false all must be suspect. Still, in many cases, the sole source of information respecting the synthetic colours lies in the patent literature and, in consequence, an author has to exercise a wise discretion in sifting and arranging all the material which comes to his hand. It follows, therefore, that the possession of a wide knowledge, not only of his subject but also of the technique of his subject, is essential if the result is to be in any way comparable with the energy expended, and, probably, no one is more fitted than the author of this work—an old and honoured worker in many of the fields he describes—to undertake the task he has accomplished so admirably.

Prof. Hewitt's work is a readable book, although it contains a mass of complex information, and its readability is due to the manner in which the author has summarised and, in some cases, criticised the material he has collected. His criticism is, however, neither carping nor hostile, but is always expressed in a detached and almost humorous manner, which is so characteristic that it cannot fail to raise a smile upon the lips of those to whom he is personally known.

Although originally intended to be a book on the acridine and xanthene colouring matters, it was ultimately found necessary to include those derived from pyridine and quinoline, and the first four chapters are devoted to a description of these bases and the colours obtained from them. It is perhaps fortunate that the change was made, because it enabled the author to include a description of the cyanine group, many members of which are important photographic sensitising dye-stuffs. The next five chapters are devoted to the acridine derivatives and contain an exhaustive account of these colouring matters. Chapter x. deals with the pyrone ring, and introduces the history and description of the oxonium salts. The subject-matter of this chapter naturally leads to a description of the colouring principles of flowers, but one finds, with some regret, that there the author breaks off and refers the reader to the previous monograph by Perkin and Everest. Surely a little overlapping in this series

of monographs is not only inevitable but desirable. The remaining chapters give interesting accounts of the pyronines and rosamines; the constitution of fluorescein and analogous compounds; the constitution of the rhodamines and their manufacture; and the chemistry of the rhodols and anisolines. Of special interest, from the general point of view, is the discussion of the constitution of phenolphthalein and fluorescein, which is given in a manner which will appeal to those students who have to approach these difficult problems for the first time.

The book is well printed and the very complex formulæ are particularly clear and easy to follow. It is stated to have been printed in Saxony, and this probably accounts for some of the quaint spelling which has escaped the vigilance of the proof-reader. "Recomends" on p. 11, "wather-bath" on p. 29, the inverted commas on p. 66, "occour" on p. 289, "preapare" on p. 269, "doubtfoul" on p. 38, "ac" on p. 56, "annother" on p. 58, "occurence" on p. 64, "alo" on p. 91, and "accridine" on p. 120 meet the eye and are perhaps inevitable in the circumstances. Moreover, it is difficult to know what the "dashes" after the names of Williams and Hofmann on p. 55 really mean. But these are minor faults, and both the author and the editor are to be congratulated on the production of a volume which will long remain the standard treatise on the subject with which it deals.

J. F. THORPE.

The Eye and Vision.

The Present Status of Visual Science. By Dr. Leonard Thompson Troland. Pp. 120. (Bulletin of the National Research Council. Vol. 5, Part 2, No. 27.) (Washington: National Academy of Sciences, 1922.) 1.50 dollars.

THE eye can be regarded as holding a unique position among the organs of special sensation, because of all methods of observation, those carried out by vision, either unaided or through the medium of suitable accessory apparatus (*e.g.* the photographic plate), are the most accurate, rapid, and susceptible of the widest application. Moreover, the problems which the eye presents for solution are of interest, not only to the physiologist and anatomist, but also to the oculist, physicist, psychologist, and the illuminating engineer, and much has therefore been written by them in their own respective spheres. So plentiful, in fact, has the literature of vision become, that a complete mastery of the subject is possible to few. Dr. Troland has therefore achieved a result of great value in the publication of the book before us.

Early in the book, and again in the concluding pages, Dr. Troland utters a word of warning; there are, he points out, too many papers published on vision. Many authors, he says, "show a lack of acquaintance with the problems and results with which the others are concerned" (p. 10), and "appear also to have a profound contempt for existing literature, even when it is in their own language" (p. 110). In many papers there is "an absence of that complete specification of all circumstances surrounding experimentation which is needed to render the results of any permanent value" (p. 110).

The reader of Dr. Troland's book will find that the pages which follow the introduction are written with three objects in view: to indicate as clearly as possible the lines of cleavage between the physiological, psychological, and physical aspects of vision; to summarise the well-established facts concerning the various mechanisms associated together in the eye; and to indicate the points where our knowledge is defective or altogether absent. Owing to the necessity for brevity it is not possible to go over all three parts of Dr. Troland's book in this review. The last one will alone be selected for detailed consideration, because it recalls some of the well-established facts of vision at the same time that it indicates the direction which future research should take.

Considering, in the first place, those eye structures which co-operate to form an image on a retina, Dr. Troland writes (p. 39): "The ophthalmoscope, the skiascope, and the corneal microscope (supplemented by Gullstrand's slit-lamp) provide us with instruments for examining the tissues of the living eye in a very satisfactory way." Elsewhere he adds (p. 40): "Helmholtz was able to work out satisfactorily the main dioptric or refractive function of the eye from data of optical anatomy, in combination with the established general principles of physical optics." The word "satisfactorily" in the above sentence unfortunately cannot pass unchallenged, because, although we know the positions of the principal points of the eye according to Gauss's theorem with considerable accuracy, and although we know that the eye suffers from certain aberrations, the data from which we can calculate the distribution of light intensity in the image formed on the retina are very deficient. Neither can we check our calculations by direct observations of the retinal image, because the structures found in the retina are insufficiently fine for the purpose, and we are unable to remove the retina and examine the image by other means without reducing the intra-ocular pressure, and thus allowing the distances between the optical surfaces to alter.

What is wanted is a method of quantitative estimation, applicable to the retinal image, no less accurate than that devised by Hartmann for studying the

aberrations of photographic objectives, which has been recently adapted to microscopic objectives also.

Reference may now be made to one other part of the dioptric mechanism, namely the "accommodation." Of this Dr. Troland writes (p. 40) that Helmholtz's theory "borders on the line between legitimate inference and mere hypothesis." In this connexion we may recall that many physiologists hold Tscherning's theory to be the correct one. In fairness to the memory of Helmholtz, it should, however, be stated that several recent workers have obtained results wholly in favour of his view.

Of the retina, and the nature of the processes by which light and colour are perceived, Dr. Troland writes (p. 43): "It is to be regretted that relatively little work upon the microscopic anatomy of the retina has been done in recent times, the epoch-making researches of Raman y Kajal having found no worthy successors." With this opinion every physiologist must regretfully agree; but will there be such unanimity over Dr. Troland's dismissal of Edridge-Green's theory in the following words?—"Views such as those of Edridge-Green, who regards the rods as non-photosensitive manufacturers of visual purple, which latter is operative only in stimulating the cones, may be dismissed at once without serious consideration." Now, however difficult it may be for some of us (who have been, as it were, brought up on the duplex theory of von Kries, which teaches that the rods function in night vision, and that while the hen has no rods and is therefore night blind, the bat has no cones and is therefore day blind) to accept Edridge-Green's hypothesis, we must feel that to dismiss it without consideration is to act too impulsively.

The criticisms which Edridge-Green advances against the older view are very weighty and worth serious thought. It is possible that, as so often in physiology, parts of both views are true and that there may be some half-way hypothesis acceptable to both parties; such, for example, as this: that while cones function principally by day for the appreciation of colour, and rods by night, yet cones do function to some extent at night, by a partial retention of the old functions of the rods from which they were presumably developed, while, on the other hand, rod vision is still to some extent operative in day vision, particularly in regions of the retina, on which are falling parts of the image corresponding to the shadows. It is only by dismissing nothing without consideration, and by research on the lines of Kuhne and of Hecht, that this important problem will be finally solved.

Much the same statement must be made concerning the appreciation of colour. New hypotheses, based on the quantum theory, are springing into being, and there are not sufficient data to enable a decision to be made between them and the older trichromatic theory of Young. Colour mixture equations would suggest that there are pigments present in the retina other than visual purple, but there is great need of direct proof of their existence and quantitative information concerning their distribution in the retina and their spectrophotometric properties. It is not the repetition, which Dr. Troland advocates, of older work that is wanted so much as entirely new lines of attack.

Many other important branches of visual science are dealt with by Dr. Troland in his book, but enough has been written here, perhaps, to show that the volume is a very real contribution to knowledge. No better incentive to future research could have been compiled; let us hope that the harvest will be a rich one.

H. Hartridge.

The Brackish-water Area of the Zuiderzee.

Flora en Fauna der Zuiderzee. Monografie van een Brakwatergebied onder redactie van Dr. H. C. Redeke en met medewerking van Tera van Benthem Jutting, H. Engel, H. C. Funke, Dr. A. C. J. van Goor, J. A. W. Groenewegen, Dr. B. Havinga, J. Hofker, Dr. R. Horst, Prof. Dr. P. N. van Kampen, Geertje de Lint, Dr. J. G. de Man, Prof. H. F. Nierstrasz, Dr. A. C. Oudemans, Prof. Dr. C. Ph. Sluiter, Dr. J. F. Steenhuis, Dr. J. J. Tesch, Dr. Adriana Vorstman, Nel de Vos, Prof. Dr. Max Weber en Dr. N. L. Wibaut-Isebree-Moens. Uitgegeven door de Nederlandsche Dierkundige Vereeniging ter Gelegenheid van Haar Vyftigjarig Bestaan. Pp. 460. (Helder: C. de Boer, Jun., 1922.) 10 guilders; for members of the Nederl. Dierk. Vereen., f. 2.50.

With the draining of the Zuiderzee one of the largest brackish-water basins of Europe, and a very peculiar one, will disappear. In the Baltic Sea, the largest of all, tidal movements are of very little importance: in the French and English river-estuaries, tides are the predominating factor, while in the Zuiderzee only a few small areas are struck by regular tidal currents, and the greater part of the southern basin is only shaken up from its lake-dreaminess by north-western gales. Therefore it was a very useful work of the Dutch Zoological Society (Nederlandsche Dierkundige Vereeniging), and specially of Dr. H. C. Redeke, the director of the Zoological Station in Den Helder, to bring together all that is known from the Zuiderzee in this monograph, issued on the occasion of the fiftieth anniversary of the Society.

In recent years a few small expeditions have been

made to increase our knowledge of the subject. As the middle part of the southern basin will not be drained, but remain open water, named Lake Flevo, we shall have a splendid opportunity of studying the changing of the brackish-water fauna into a fresh-water community. We do not know how long this will take, but, seeing the amount of water that is brought to the Zuiderzee by the river Yssel, it is almost certain that the days of the brackish Zuiderzee will be counted as soon as the dike between the provinces of Holland and Friesland from Wieringen to Piaam is ready, which will take another ten years. Nevertheless, we must be very glad that the research work has begun in such splendid style.

In the first chapter, the geology and hydrography are treated by Steenhuis and Redeke respectively. The geology is, of course, for the most part based on historical facts, as we know that two thousand years ago there was no Zuiderzee, but a Lake Flevo, as there will be again at the end of this century. The reason for this victory of the sea over the land must lie in the change in relative height of land and sea-level. The author does not give his opinion, however, about the cause of these changes. The hydrography, treated by Redeke, is of extreme importance, as we find here tables of temperature and salinity of the water in different parts of the basin during all seasons of the year. The lowest salinity (4 to 8 *per mille*) is found along the east coast, where the Yssel water flows, and causes a constant stream in a northerly direction.

The flora of the Zuiderzee is treated by Dr. van Goor, and the halophytes and submerged Phanerogams, the Algæ, and the phytoplankton are dealt with successively. Some fifty species of Algæ were collected, among them some that were previously unknown in the Dutch flora. The most important, however, is a new form of Fucus, baptised *F. intermedius*, nov. spec., which is intermediate between *F. vesiculosus* and *F. platycarpus*, and still not to be identified with the *Fucus ceranoides*, the brackish-water form of the French coast, which occurs also in the Schelde River. It should be of great interest to study the Fucus growth in Breydon Water, Hudson Bay, etc., to compare and try to find out more particulars of the distribution and life-history of this interesting group.

A comparison between the flora of the Baltic and Zuiderzee gives the interesting result that, while in the Baltic Cyanophyceæ and Peridiniales form by far the greatest part of the planktonic organisms, in the Zuiderzee the Diatoms play the most important rôle. The Copepod fauna of the Baltic and the Zuiderzee is much the same, but in the phytoplankton there is a difference even in the genera of the most important species.

The Protozoa are treated by Hofker, who gives a well-illustrated review of the specimens collected, which is of great value, as hitherto very little work has been done in Holland on these groups. Especially his account of the Foraminifera will prove a great aid for further investigation. It is highly probable that this shell-bearing group will furnish in later years just as good methods for analysing alluvial and diluvial deposits as diatoms already give. It is a great pity that the publication is merely systematic and morphological, for comparison with other faunas and a partition in salinity groups would have been of the greatest importance. We hope that this part of the work will follow, and point out that van Goor did it for the flora, Funke for the hydroids (twelve species), Geertje de Lint for Cladocera and copepods, etc.

Dr. de Man treats the free-living nematods, and describes among his forty-nine species no less than twelve that are new for science. For particulars I must refer to the publication itself. Twenty species of polychæt annelids were collected, and are treated by Dr. Horst; five species of Oligochætæ, described by Nel de Vos, while Dr. Wibaut-Isebree Moens shows that several Rotifera occur in fresh as well as in brackish water. Then we come to that important group, the Crustacea, important from the fisherman's, and therefore from the scientific point of view, as they have been very thoroughly studied recently. I have already mentioned the Cladocera and Copepoda, studied by Geertje de Lint. A new species of Schizopera is described.

Spongiæ, Cirripeda, Isopoda, Amphipoda, and Schizopoda are all treated, but show no special characters. Among the Decapoda, analysed by Dr. J. J. Tesch, *Leander longirostris*, called the Rhineprawn by British carcinologists, was found only once in the Zuiderzee. The life-history of the specific little Zuiderzee crab, *Heteropanope tridentata*, is very interesting; its only allies live in the tropical Pacific, and it has not been studied before. Illustrations of the larval states will prove very useful in recognising this interesting little creature.

A new Acaris is described by Oudemans; Havinga treats the marine Mollusca, of which several are of importance, as food for fishes and men. *Cardium edule* and *Mya arenaria* have typical brackish-water forms and measures. Among the fresh- and brackish-water Mollusca treated by Tera van Benthem Jutting is the famous *Corambe batava*, Kerbert, found for the first time in 1881; it appears to be not at all rare on the Zostera meadows of the Zuiderzee. Eggs and radula are described and represented. *Assemania grayana* appeared to be a sexual dimorph, the male being much smaller than the female, and being usually

found in summer riding on the weaker sex. Among the Bryozoa, treated by the same author, we find the beautiful *Membranipora membranacea* var. *erecta*, which is very common in brackish water in Holland.

Echinoderms and tunicates must be passed here for lack of space. Dr. Redeke's account of the fishes will be of special interest, not only to ichthyologists, but also to others, for here the different zones of salinity are separately described. Last comes Prof. Max Weber, who treats of ten species of cetaceans, of which specimens of all but one, the common Phocæna, have stranded on the banks of the Zuiderzee at different times.

A systematic index, more than eight pages in three columns, increases the utility of this important monograph of a brackish-water area.

W. G. N. VAN DER SLEEN.

Geology for Canadian Students.

Elementary Geology: with special reference to Canada. By Prof. A. P. Coleman and Prof. W. A. Parks. Pp. xx+363. (London and Toronto: J. M. Dent and Sons, Ltd., 1922.) 15*s*. net.

THE issue of treatises on general geology specially adapted to readers and observers in the units of our federal commonwealth is a sign of healthy autonomy in the domain of natural history. Colleges in the Dominions have long been troubled with the details of the English Oligocene, a poor thing at the best, or the Llandovery sequence on the Shropshire border. Aspirants in South Africa have been well served by Mr. A. L. Du Toit's "Physical Geography" and Prof. E. H. L. Schwarz's "South African Geology," since the latter includes a short general introduction to the science.

Profs. A. P. Coleman and W. A. Parks of Toronto now provide Canadian students with a sound elementary text-book based primarily on what may be seen in Canada or in the adjacent United States. The account of the Grenville and Keewatin series, the former consisting of altered shales (garnet-sillimanite gneisses) and crystalline limestones, and the latter of volcanic tuffs and lavas, is very valuable for European students who wish to realise the nature of the oldest known rocks revealed to us in the accessible crust. The eastern series, the Grenville, may prove to be somewhat older than the Keewatin of the west; but both are invaded by the great batholitic intrusions which have given rise, often by interaction with their surroundings, to what may still be styled the Laurentian gneiss. Prof. Coleman's work among the glacial beds of early Huronian age adds greatly to the interest of the pages on Pre-Cambrian rocks.

While European types of fossils are in places very justly figured, such as the Jurassic Trigonias and ammonites of England, we are introduced to the Cambrian trilobites of British Columbia, to Devonian fishes from Canada described by Traquair and Whiteaves, to the Permian reptile Dimetrodon of Texas, with its amazing dorsal spines, and to a Lower Cretaceous Stegosaurus from the province of Alberta. The Cainozoic era, styled also in this book the Tertiary period, is dealt with slightly; yet the thicknesses of its strata in many localities show that its duration was equal to that of Mesozoic times. The spelling "Cenozoic," adopted by the authors, though it follows Lyell's nomenclature of the systems, is etymologically misleading and should be synonymous with azoic. We greet on p. 353 an ancestor of the national maple leaf, culled from interglacial deposits in Toronto.

The book is finely printed and is handsomely illustrated throughout. Too much may have been attempted in one volume, and the definitions of divisions of the animal and vegetable kingdoms on pp. 155-160 are necessarily unsatisfying and incomplete. Some of these divisions are further treated in the chapters on stratigraphy; but where are the radiolaria, which have a significance as rock-formers? Five or six pages more would have made the description of mineral characters almost adequate. As it is, we have a not too accurate summary of the crystallographic systems (the principal axis, for example, in the tetragonal and hexagonal systems is said to be "long"), while we are led to suppose that quartz is hexagonal. Are the micas, again (p. 12), of different crystal systems? "Mont Pelée," an error sanctioned by Angelo Heilprin, appears under the fine photograph on p. 54. These are small details, and to point them out implies that we know that new editions will be required, and that the next one will still further enlighten us by the possession of an index.

GRENVILLE A. J. COLE.

Mental Athleticism.

Principles of Psychology: the Foundation Work of the Alétheian System of Philosophy. By Arthur Lynch. Pp. xxiii+408. (London: G. Bell and Sons, Ltd., 1923.) 21*s*. net.

MR. LYNCH some years ago published a book in two volumes entitled "Psychology: a New System." Whether, like a famous work of a famous predecessor—the Scots philosopher Hume—his book fell still-born from the press, or whether for other more personal reasons, he has decided to recast it. He now presents it in one volume and describes it as the foundation work of the Alétheian system of philosophy. (Why the first e in the word is given the French acute

accent we do not know.) The choice of the name seems to imply a slight on other systems, but probably nothing of the kind is intended, and it is only an expression of the author's boisterous confidence in his own powers.

The personal note is predominant throughout and makes it peculiarly difficult to discuss the doctrine, and impossible to controvert any of the positions. Of course, in psychology, the personal experience carries a peculiar weight. What Mr. Lynch explains to us is how he won his way to the possession of the clear mental grasp of the problem he now enjoys; how he overcame the stumbling-blocks he had to encounter in the perversity of authoritative teachers; how these obstructions actually served him to gain his vantage-point; and how we, if we will follow him, may become mental athletes also. Naturally his appeal is to the young. The curious thing to the older reader is that the solution offered as new is certainly not novel. We are to find the fundamental processes of mind in the same way in which the chemist and the physicist find the fundamental processes of matter. Having discovered them we shall find for the science of psychology, as they find for the sciences of chemistry and physics, that construction follows naturally. Very good, we may think, at any rate as a preliminary discipline,—but then Mr. Lynch does not set his followers to look for these fundamental processes, he puts in their hands the list of them. The processes are twelve in number, and the proof that they are fundamental and that the list is exhaustive is that Mr. Lynch has himself verified that they are so.

The reader will find an enormous number of references to other writers and an extensive survey of science in all its branches. Special importance is attached by the author to the section on memory, the whole of which is based on careful observations and experiments in connexion with his own personal experience.

Our Bookshelf.

John Penrose: a Romance of the Land's End. By J. C. Tregarthen. Pp. vi + 342. (London: J. Murray, 1923.) 7*s.* 6*d.* net.

It is not often that a book of fiction comes within the class of literature appropriately noticed in NATURE, but Mr. Tregarthen includes in his delightful romance of "John Penrose" so many interesting sketches of the wild life of the Land's End peninsula that we feel justified in recommending the book to all students of natural history.

Those who know West Cornwall must recall many an old man such as John Penrose was when the local parson inspired him to "put down" his recollections as the not uncommon farm boy who is keenly observant of the habits of the many pests, and a few wild friends, of the farmer working a small patch of land adjacent to an unreclaimed moorland. The wild animals come into the story as naturally as the human characters, and, with references to them, the author records many old local customs and beliefs that are in danger of being forgotten, as well as sayings and expressions of the old folk which are in danger of becoming obsolete through the influence of the modern school teacher, who, too often, gives his pupil the impression that old English provincialisms are vulgarisms inconsistent with modern education.

Not the least interesting among the conclusions to be gathered from the incidents described is the local attitude of highly respectable people to smuggling: to be entrapped by the preventive officers carried its measure of disgrace, but neither the otherwise rigidly honourable yeoman, nor even the parson, thought it wrong to conceal information about smuggling.

It is not easy to avoid anachronisms when writing autobiographically about a past period, and Mr. Tregarthen has not succeeded in avoiding every pitfall. In referring to the miners who had returned from the gold diggings of California the author recalls a familiar feature of West Cornish life in the 'sixties and 'seventies, but the incidents which he describes on pp. 2, 65, and 68 obviously refer to a period before 1848, the year in which the first Californian gold fever actually started.

T. H. H.

The Annual of the British School at Athens. No. 24. Sessions 1919–1920; 1920–1921. Pp. viii + 280 + 14 Plates. With Supplementary Paper No. 1: *The Unpublished Objects from the Palaikastro Excavations,* 1902–1906. Described by R. C. Bosanquet and R. M. Dawkins. Part 1. Pp. xii + 160 + 34 Plates. (London: Macmillan and Co., Ltd., 1923.) 63*s.* net.

THE article of most general interest in this excellent number is that by Mr. C. A. Boëthius on primitive house types as illustrated from Mycenæan and Nordic structures. The results of recent excavation on prehistoric Greek sites show that there is no evidence to support, still less to prove, the widespread assumption that the round hoop-roofed house is the original type from which all forms of human houses have been evolved. There is a considerable variety of primitive forms, and both rectangular and round huts and houses occur contemporaneously in ancient times and at the present day among primitive races. In Greece the neolithic material shows that well-developed round huts and equally advanced rectangular houses were contemporaneous. In Sweden we find round huts, possibly developed from a primitive tent or a screen against wind and rain. In the Bronze Age come oval houses developing into the rectangular form. "The evidence of primitive European dwellings shows, besides round tents or huts and pent roof structures, horseshoe screens with a fire in front of them, and rectangular screens with their various forms of development centring on the fire. Anywhere in Europe, climate and material can thus suggest a beginning which leads to a round hut, a horseshoe-shaped hut, or a rectangular hut with a central or eccentric hearth, and door at one end. A rectangular house with a central hearth can be just as elementary as a round or horseshoe-shaped neolithic hut, and of entirely independent origin."

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Micelle—A Question of Notation.

THERE is a class of colloids, recognised as a class for very many years, in which the substance is a salt of an ordinary ionisable type the peculiarity of which consists simply in a prodigious disparity in size and solubility between the two parts of the salt molecule. Such are many proteins, some dyes, and soaps, to enumerate them in the order in which they have been investigated. What all colloids do surreptitiously, namely, take to themselves uncovenanted ions, these do in an honest straightforward chemical fashion.

The properties of the class *qua* colloids were, I believe, first worked out by myself in the years 1898–1905, the special case examined being certain proteins, called globulins, which present the added complexity that they combine not only with acids and alkalies to form salts, but also with neutral salts themselves. In spite of this, when the large number of variables was disentangled, the behaviour of the substances was found to be singularly orderly, the phase-rule diagram, for example, being strikingly like that of a commonplace three-component system bearing no suspicion of colloidality.

These colloid salts present one striking peculiarity, namely, that though in water they ionise and hydrolyse on the whole according to the approved pattern, yet one of the molecular species, and that the one which confers upon the solution its most characteristic qualities, is a complex composed for the most part of undissociated salt molecules but with a surface electric charge due to ionisation at the surface.[1] To these bodies I gave the name "colloidal ions." This is strictly accurate notation, for it is because of these complexes that the solutions possess the characteristic colloidal trick of slurring over the obligations of the chemical law of definite and multiple proportions, and they are ions as Faraday used the word, for they wander (ἰόν) in an electric field.

I pointed out that they conformed to Helmholtz's analysis of the condition of electric endosmose, the density of the charge on the surface being constant, and the total charge, therefore, proportional to the surface area. This, of course, obtains only when the solution has had time to forget its past history and to come into equilibrium; waiting for which state needs, in colloidal society, a vast gift of patience.

In the years which followed, much excellent work was done on another example of the group, namely, congo red, by Bayliss, who described aggregates of anions, the total charge being the sum of the charges of the constituents; and still later, a third example, namely, ordinary soap, was investigated by McBain, who rediscovered the colloidal ion but christened it "micelle."

Now accuracy of notation is the breath of the life of science, and to use the word "micelle" for a colloidal ion seems to me to be positively wrong, since the word was introduced by the botanist Nägeli in 1877 to describe something entirely different. Nägeli was a man of a curious imagination but he clothed his dreams in exact language. He is precise as to what he means by "micelle." The word was coined amid a controversy which raged in the 'seventies and 'eighties concerning a distinction then drawn between organised and unorganised colloids and the causes of "swelling."

Nägeli, who was an intellectual heir of the Frankenheim of 1851, began with molecules in 1858, but by 1877 he had identified the unit of the colloidal state as an aggregate of composite type to which he gave the name "micelle." This he supposed to consist of a nucleus of solute surrounded by an atmosphere of bound water. The water atmosphere was the essence of his conception, which had nothing to do with electric charges or with ionisation. A single "micelle," or a micellar chain, contained a micellar nucleus, or nuclei and micellar water. A gel was conceived as being composed of such chains with their micellar water, disposed as membranes or bars to form a sponge enclosing extra-micellar or "enclosed" water.

In complete opposition to Nägeli was Strasburger (1882), a molecularist in the direct line of descent from Kekule. Between stood Pfeffer, whose forebears were Dutrochet, 1827, Nägeli of 1858, Graham, 1864, and Traube, 1867; van Bemmelen had no kinship with Strasburger, he follows on the latest stage of Nägeli (1880) and Pfeffer.

I have just been looking through my thirty-year-old notes of that discussion. What a lot those people knew which is now forthcoming as new knowledge! They knew, or at any rate conjectured, that the colloidal particles were strung together in thread-like masses in some colloidal solutions, and it will do no harm to remind those who propound theories of gel structure that they knew such theories must account for hydrostatic pressures of upwards of 45 atmospheres.

The colloidal ion is far removed from Nägeli's "micelle"; it is nearer to the supposed colloidal unit which Pfeffer called a "tagma," and described as an overgrown aggregate of one species of molecule, namely, those of the solute.

Had recent workers known of these earlier hypotheses they would possibly have been content with the words "colloidal ion" for the constitution of soaps. That brings me to the gist of the matter: in the early 'nineties when, as a physiologist, I was attracted to colloids, I found two schools, both of whom had done excellent work, wholly unacquainted with each other's writing. Ringer, for example, on the biological side had demonstrated on the living heart the differential action of ions and "antagonism." He did not recognise the full significance of his observations because, like all contemporary biologists, he was wholly ignorant of the work of Schulze, and of Picton and Linder. The two schools presently came together to the advantage of both, but now the striking want of acquaintance by many chemists with colloidal work published in the biological journals is symptomatic of a renewed falling apart. How many physicists or chemists know of Mines's brilliant work on membrane potential?

It is impossible to avoid rediscoveries in science because of the enormous burden of knowledge, but it is in every one's interest to minimise them. Out of the mouth of a sinner comes, I hope, good advice. I must be the greatest of sinners myself, for it is certain that no one reads other people's science with greater reluctance than I do.

W. B. HARDY.

[1] A most interesting suggestion as to their structure is that of Adam, in the Proc. Roy. Soc., A, xcix. 336, 1921.

Problems of Hydrone and Water: The Origin of Electricity in Thunderstorms.

THE subject of the electricity of rain and its origin in thunderstorms was dealt with by Dr. G. C. Simpson in a communication to the Royal Society in 1909 (Phil. Trans., 1909, A, vol. 209, pp. 379-413). Taking

Lenard's observations and his own experiments into account, Dr. Simpson concludes that it is not an induced effect, due to an external source; he considers that there is an actual production of electricity in the *subdivision* of large raindrops.

Dr. Simpson's conclusion has long been in my mind. Latterly, the subject has been an attractive one to me, on account of the views I have formed of the composition of water and of the chemical changes attending alteration in the size of drops, referred to in my recent communication to the Royal Society (Roy. Soc. Proc. A, vol. 103, p. 616, 1923). I was much impressed by a lecture at the Royal Institution given early in the year by Dr. Simpson (NATURE, April 14); this, together with a violent hail-thunderstorm which I experienced while yachting in August, led me to look more closely into the problem.

Assuming that water be the cause, the view I should be inclined to take is the converse of that advocated by Dr. Simpson. Granting, for the sake of argument, that changes in water can give rise to free electricity, the fusion of small drops into large would seem to be the more likely process—this being a positive change, in the sense that energy is liberated, while the division of large drops should involve a loss of energy. I assume that the small drops are richer in hydrone than the larger and that changes in composition of the water take place such as I have postulated in my recent communication.

Going further, however, can it be granted that chemical changes *in a wholly liquid circuit* ever give rise to sensible electricity—must not the circuit *be tapped by conducting electrodes* to make this obvious? We must assume that the interactions are primarily electrolytic, but is not the electrical energy, in such cases, always lowered into heat energy?

The question is of fundamental importance, and it is on this account that I make bold to be critical of a solution of a problem outside my field; yet it is one of the borderland issues which chemist and physicist should jointly consider.

Assuming that my interpretation be correct, may not the great rise in potential required to produce lightning have its origin in the coalescence or co-operation of minute drops charged by an external source?

Lenard (*Wied. Ann.*, 1892, 46, p. 584) dealt with the effect, in the first instance, in studying the electricity of waterfalls. His later laboratory experiments led him to the conclusion that it was due to the impact of separate drops upon a flat surface. The water was allowed to splash *into a zinc tray*. Both he and Dr. Simpson found it necessary to use distilled water; that from the mains gave little or no result. The air potential observed was negative, but with a solution of salt it was slightly positive. Up to a certain point, the potential increased rapidly with the length of the jet. Various liquids other than water were tried: the potential varied in sign and magnitude, but the effect was slight as compared with the water effect. Lenard seems to think that the effect has its origin in a contact difference of potential between gas and liquid. All seems to me to point to chemical interchange being at the root of the phenomena and that it is not a mere water effect.

HENRY E. ARMSTRONG.

Earthquake Warnings.

THE recent disaster in Japan demonstrates the importance of endeavouring to ascertain if there are any premonitory indications of a coming earthquake shock which can be recognised and thus enable a warning to be given of its approach.

It seems probable that the rupture, whatever its nature may be, that gives rise to the actual vibratory shock of an earthquake is preceded by a strain or distortion of the earth's crust, which gradually increases till the stress that causes it is suddenly released. The existence of this strain should be evidenced by a progressive sag or tilt of the surface, local and minute in amount, no doubt, but probably sufficiently large to be detected.

In the Milne-Shaw seismometer the vibrations proceeding from distant earthquakes are recorded on sensitised paper on a rotating cylinder by a spot of light reflected from a mirror coupled to the boom of a horizontal pendulum. Ordinarily it is only these vibrations that are taken into consideration, but the same instrument will also indicate a slow tilt of the ground, provided that the exact position of the spot of light can be recorded and measured. In some instruments recently constructed, one of which is being installed in Uganda, this is effected by the use of a second, stationary mirror, which throws another spot of light in a fixed position on the cylinder, and traces a straight line on the record. If there is a tilt of the earth's surface it will be indicated by a variation in the distance between the mean position of the line due to the moving mirror from that of the line due to the fixed mirror, unless of course the tilt is in a direction parallel to the horizontal pendulum. Such an instrument is capable of showing a tilt of $\frac{1}{15}''$ by a movement of the indicating spot of light through 1 mm. If two instruments are employed with their horizontal pendulums at right angles to each other the direction and amount of the tilt will be exactly determined. Near the sea the rise and fall of the tide causes a slow tilt and other changes of a slow periodic character are known, but these can be allowed for and could easily be distinguished from a progressive movement indicating the approaching occurrence of an earthquake in the neighbourhood.

It seems very desirable that such instruments should be installed in localities which are known to be subject to earthquakes.

If it be found that shocks are in fact heralded by a definite tilt, it may be possible to arrange for an electric bell to attract the attention of the observer when such a tilt occurs. If he is satisfied that there is sufficient evidence of an approaching earthquake, a general alarm can be sounded. In this way a warning might be given several hours, or even days, before the shock occurred.

Human Embryology and Evolution.

IN his reply to Prof. MacBride (NATURE, Sept. 8) Sir Arthur Keith states that in his Huxley lecture he neither affirms nor denies the doctrine of use-inheritance, but that he does deny that Lamarckism has had no part in the evolution of man. If these words were to be taken literally as expressing Sir Arthur Keith's meaning, he and I would be to a great extent in agreement, but it is obvious that the double negative was an accidental mistake, and that Sir Arthur Keith meant to deny that Lamarckism had *any* part in the evolution of man.

I have read the report of his Huxley lecture to the medical students of Charing Cross Hospital Medical School (NATURE, Aug. 18), and it seems to me difficult for an evolutionist to follow his train of thought or reasoning. He does not distinguish between the development of the individual and the evolution of the race, between ontogeny and phylogeny. He discusses the manner in which adaptations appear

during the development of the human embryo, taking as examples the development of the eye, of young nerve-cells, of muscular adaptations. In the adult human leg the peroneus tertius is separate in 90 per cent. of cases, having thus an advantageous position for the performance of its function in walking. In the anthropoid apes this muscle is quite unseparated from the long extensors of the toes. In the developing human fœtus the rudiment of the peroneus tertius separates from the long extensors with which it was originally continuous. To most biologists this would be a typical case of recapitulation.

Sir Arthur Keith says he agrees with Huxley that there are no grounds for believing that the behaviour of embryonic muscle cells is in any way influenced by experiences gained by adult muscle fibres. He then makes the statement that "The evolutionary machinery lies in the behaviour of the embryonic muscle cells or myoblasts," which to me, as it stands, is quite unintelligible. The behaviour of the embryonic muscle cells can explain nothing but the mode in which the adult structure is developed. Such behaviour begins and ends with the individual organism, and cannot possibly contain any evolutionary machinery. It is merely one detail of the complicated embryological changes by which the adult structure is developed. In relation to evolution the question is how are we to explain the fact that the "behaviour of the embryonic cells" is different in the human fœtus from what it is in the anthropoid apes, which presumably resemble the ancestral condition? On this question Sir Arthur Keith says nothing, except the assertion quoted of his agreement with Huxley.

In another part of his lecture Sir Arthur Keith discusses the action of hormones in the course of ontogeny in co-ordinating the development of different parts and tissues. He concludes that more complete knowledge "will reveal in full the true nature of the machinery which underlies the production of structural adaptations which occur in every part of the animal body in every stage of its evolution." Here, again, he is confounding the evolution or origin of the adaptations with their mere development in the individual.

Nevertheless, Sir Arthur, while denying the influence of external influences in human evolution, admits the heredity of "acquired characters" and even injuries in certain cases. He states that Lamarckism cannot explain the characters which differentiate one racial type of modern man from another. On this last point I am entirely in agreement with him, for Lamarckism is a theory of the evolution of adaptive characters, and racial characters of man are for the most part not adaptive.

I should like in conclusion to contrast two passages in Sir Arthur Keith's lecture. He writes, "Nothing is better known than that, if a bone of a rickety child bends under the weight of the body, the bone cells lying in its concavity will proliferate and build a buttress to strengthen the shaft." The bone cells "react to fulfil an end necessary for the occasion." This seems to me quite inconsistent with the statement, "there are no grounds for believing that the behaviour of embryonic cells is in any way influenced by experiences gained by adult muscle fibres." The first of these two passages admits the *reaction* of the tissues of the body to external stimuli, while the second passage and the whole tendency of the lecture apparently denies the occurrence of such reaction.

Curious Spherical Masses in Ashdown Sands.

Mr. Harry E. Burns, of Crowborough, this spring informed me of some remarkable spherical masses of sandstone in the Ashdown Sands at High Hurst Wood Quarry, and was good enough later to supply one about 10 inches in diameter to our Museum. He suggested that they might be sand casts of reptilian eggs like that of the Iguanodon. They consist of fine-grained nearly white stone—much of the iron having been leached out. I expected but failed entirely to find on section any pan or stains of limonite such as in the well-known balls of Folkestone Sands.

Recently I have visited the quarry with Mr. Burns, and was able to see a ball 30 inches in diameter in position. We were told they are confined to an upper bed about 14 feet thick, and vary in size from 10 to 30 inches in diameter. We could discover no evidence

Fig. 1.

of a foreign body or of concretionary growth, although such growths are not rare in the Wealden Sandstones—often, too, in a decalcified condition. Those at Crowborough are found loose in a narrow cavity, and the stone appears identical in colour, etc., with that of the surrounding bed. The adjacent stone for a few inches is shattered—due, I suppose, to the pressure of overlying beds against the unyielding sphere, while the narrow clefts are filled with clay, doubtless washed there from the once overlying Wadhurst Clay. Strangely enough, some of these balls have been used as ornaments at the tops of wooden gate-posts! During the forty-five years I have lived in the neighbourhood I have not met such masses before, and find them difficult to explain. The photograph (Fig. 1) shows a group of these stones taken by Mr. Burns, who kindly allows me to use it.

Stereoisomerism among Derivatives of Diphenyl.

Dr. Turner's remarks (Nature, September 22, p. 439) appear to have been made without his having seen my letter of some eighteen months ago (Nature, May 6, 1922, p. 581), which was concerned with the importance of stereoisomerism among diphenyl derivatives in relation to Sir William Bragg's conclusions as to the molecular structure of benzene in the crystal. At that time, reasons for reviving the Dewar para-linkage formula for benzene had not been published (Ingold, Trans. Chem. Soc., 1922, 1143), but since this bridged formula "is stereochemically

identical with the disposition of atoms suggested by Sir William Bragg for the molecule of benzene" (Challenor and Ingold, Trans. Chem. Soc., 1923, 2068), it will scarcely be maintained that Dr. Turner's suggestion of a possible stable para-linkage in diphenyl derivatives introduces any essentially novel consideration to the question of the structure of these compounds. I also referred in my letter to the remarkable behaviour of diphenyl towards ozone, mentioned by Dr. Turner, as well as to certain other noteworthy properties of the compound.

It should perhaps be pointed out that although, as Dr. Turner states, the formula considered by him contains four asymmetric carbon atoms, it would be incorrect to suppose that it therefore demands the existence of a correspondingly large number of stereoisomeric forms of 2 : 2′-derivatives of diphenyl. For the respective distributions of the groups attached to the pair of asymmetric carbon atoms in either benzene nucleus are not mutually independent, so that only one asymmetric atom in each nucleus is effective as a source of stereoisomerism.

In conclusion, I need scarcely say that experiments on the isomerism in question are being actively prosecuted in this laboratory, and are by no means limited to 2 : 2′-derivatives of diphenyl.

J. Kenner.

Waves and Quanta.

The quantum relation, energy $=h\times$ frequency, leads one to associate a periodical phenomenon with any isolated portion of matter or energy. An observer bound to the portion of matter will associate with it a frequency determined by its internal energy, namely, by its "mass at rest." An observer for whom a portion of matter is in steady motion with velocity βc, will see this frequency lower in consequence of the Lorentz-Einstein time transformation. I have been able to show (*Comptes rendus*, September 10 and 24, of the Paris Academy of Sciences) that the fixed observer will constantly see the internal periodical phenomenon in phase with a wave the frequency of which $\nu=\dfrac{m_0c^2}{h\sqrt{1-\beta^2}}$ is determined by the quantum relation using the whole energy of the moving body—provided it is assumed that the wave spreads with the velocity c/β. This wave, the velocity of which is greater than c, cannot carry energy.

A radiation of frequency ν has to be considered as divided into atoms of light of very small internal mass ($<10^{-50}$ gm.) which move with a velocity very nearly equal to c given by $\dfrac{m_0c^2}{\sqrt{1-\beta^2}}=h\nu$. The atom of light slides slowly upon the non-material wave the frequency of which is ν and velocity c/β, very little higher than c.

The "phase wave" has a very great importance in determining the motion of any moving body, and I have been able to show that the stability conditions of the trajectories in Bohr's atom express that the wave is tuned with the length of the closed path.

The path of a luminous atom is no longer straight when this atom crosses a narrow opening; that is, diffraction. It is then *necessary* to give up the inertia principle, and we must suppose that any moving body follows always the ray of its "phase wave"; its path will then bend by passing through a sufficiently small aperture. Dynamics must undergo the same evolution that optics has undergone when undulations took the place of purely geometrical optics. Hypotheses based upon those of the wave theory allowed us to explain interferences and diffraction fringes. By means of these new ideas, it will probably be possible to reconcile also diffusion and dispersion with the discontinuity of light, and to solve almost all the problems brought up by quanta.

Louis de Broglie.

Paris, September 12.

The "Concilium Bibliographicum."

In the commentary added to my letter concerning the "Concilium Bibliographicum" which appeared in Nature of June 30, p. 880, some doubts were expressed regarding the continuous appearance of its cards. May I be permitted to emphasise again that our cards are issued and delivered as heretofore to our subscribers.

Another publication of the Concilium is the "Bibliographia Zoologica," of which volumes 30 and 31 have been published and vol. 32 will be sent out shortly, indicating definitely that this zoological bibliography is not a new undertaking of the Concilium.

No doubt it is a rather complicated question to decide whether or not this zoological bibliography in book form is a duplication of the "Zoological Record." It must be recalled that apart from completeness, promptness, and accessibility, carefulness and the procedure in the arrangement of the bibliographical work play a very important rôle. Indeed, as for every application of scientific procedure, it is not only the tools but also the degree of ability to use them which governs the appreciation of those who have to work with them. One works better with one method, another is more adapted to the use of another. To all these points have to be added as important factors the influence of different education and local tradition.

In making a plea for a co-operation between the "Zoological Record" and the bibliographical service of the Concilium, a condition which unquestionably could be of real value to the zoological world, the writer wishes to suggest that these various important points of internal character be seriously considered.

When it was decided in 1921 to continue the book-form of the "Bibliographia Zoologica," the material to be published was so extensive that it was impossible to treat the whole animal kingdom in every volume. But this is certainly not a misfortune, for it is evident that a bibliography of titles has not only an immediate value, but also represents to a great extent a source for continuous reference.

J. Strohl,
Director of the "Concilium Bibliographicum."

Zurich.

Long-range Particles from Radium-active Deposit.

In the letter which appeared in Nature of September 15, p. 394, under this heading, by Dr. Kirsch and myself, there are two errors which obscure the sense of our communication. The maximum range of the H-particles expelled from silicon should read 12 cm., the corresponding number for beryllium being 18 cm., instead of vice versa. The last sentence should read: "Our results seem to indicate that an *expellable* H-nucleus is a more common constituent of the lighter atoms than one has hitherto been inclined to believe," the word in italics being omitted in the printing.

Hans Pettersson.

Göteborgs Högskola, Sweden.

[The transposition of the values 12 cm. and 18 cm. was the fault of our printers; and we much regret it. The omission of the word "expellable" was due to the authors, who did not include the word in their letter. Two separate proofs of the letter were sent to Dr. Kirsch at Vienna, but neither was returned.—Editor, Nature.]

The Management of Medical Research.[1]

By Sir RONALD ROSS, K.C.B., K.C.M.G., F.R.S.

TWENTY years have now elapsed since I had the honour and pleasure of addressing Anderson's College Medical School at the opening of its winter session of 1903. This is, indeed, only a short interval in cosmic time; for—to use a figure which will exhibit the rapidity of scientific advance nowadays—all these years amount only to twenty vibrations of the electron which we call the earth round its nucleus the sun, in this atom which we name the solar system! However, for us it has been a considerable period. Many of those who faced me twenty years ago as students are now placed in the seats of the mighty, and will, I hope, support what I have to say to-day. Alas! two of the faces with which I was then familiar are missing—Prof. R. S. Thomson, dean of the Medical Faculty, and Sir James Marwick; some of the distinguished men who were helping us—Dr. Laveran, Dr. Robert Koch, Sir Patrick Manson, Sir William Osler, Lord Lister, Sir Alfred Jones, Sir Rubert Boyce—are no more; and, above all, I must mourn that great pupil of the School, a ruler of many Colonies, and my own master, friend, and supporter, Sir William MacGregor.

On that occasion my address was entitled "Medical Science and the Empire," and in it I described the efforts which we were making to reduce malaria in British possessions. Four years previously we had verified, corrected, and completed the old conjectures that malaria is carried in some way by mosquitoes; and three years previously the Americans had proved the similar conjectures regarding yellow fever. Schools of Tropical Medicine had been established in Liverpool and London, and were about to be created in many parts of the world. At that time I myself hoped that malaria would be banished in a few years from all our principal cities in the tropics; and I had visited West Africa from Liverpool on three occasions for that purpose. I shall never forget the assistance rendered during my second and third visits by two Glasgow men, the late Mr. James Coats, who gave us two thousand pounds to start our anti-malaria work in Sierra Leone, and Dr. M. Logan Taylor, who remained in West Africa for two years, carrying out the practical measures and trying to persuade the local authorities to continue them.

My address—which I believe was not published, but which I still possess—was full of that morning enthusiasm. I argued that the time had already come when medical science could revolutionise the tropics; when it could render them worth living in by banishing the great endemic diseases which overshadowed them; when it could assist civilisation (coming from the temperate regions of the earth) to conquer the rich regions of the Sun and of the Palm. I even dared to quote the great words of the poet regarding Columbus, that he

> "Gave to man the godlike gift of half a world;"

and I hoped that we should be able to do the same. This had been the faith which had compelled us—others besides myself—for many years: not to add to abstract science, not merely for the sake of parasitology or entomology, not to compile text-books or to fill libraries; but to help the sick and the dying—millions of them—and so to open up the world. When I last spoke to you I hoped that all this was going to be done in a year or two! I am wiser now. Kipling says that we must not try to hustle the East; so, I have found, we must not try to hustle the West either! Men think slowly. It requires a new generation to understand a new idea, even the simplest one.

Some notable advances have, however, been made. Mosquito-reduction against malaria was first urged and defined by us in Sierra Leone in 1899; and was commenced there by Logan Taylor and myself two years later in 1901, and, almost simultaneously, by the Americans under W. C. Gorgas in Havana, and by Malcolm Watson in the Federated Malay States. In 1902 Sir William MacGregor and I visited Ismailia on the Suez Canal—with the result that malaria was banished from that town within a few months. Then the Americans commenced the construction of the Panama Canal, with Gorgas as chief of their sanitary staff, and kindly asked me to visit Panama in order to see them at work in 1904. The result is well-known—the Canal is now finished, with a minimum loss of life. But you are probably not so familiar with the equally great work of Malcolm Watson in the Federated Malay States—because it is merely a British achievement! For more than twenty years he and his friends have fought on against King Malaria and all his allies—rain, heat, jungle, marsh, and ignorance—and is gradually winning forward, step by step. While Gorgas had behind him the full official support of the wealthy American nation, Watson and other British workers in this line have been mostly obliged to rely only upon private initiative and such small funds as they could rake together for their purpose. Not less important has been the work of the entomologists, from F. V. Theobald onwards; but I am not now narrating the history of this movement, or I could speak of many other brave efforts made during these last twenty years. Not perhaps quite as much as I had hoped for, but still something. What may be called "economic sanitation" among our troops, our officials, and our large and numerous plantations, has been greatly improved, and thousands of lives and thousands upon thousands of cases of sickness have been saved. Perhaps, even already, we may echo the words of the Duke of Wellington: "Yes, 'twas a famous victory."

During the same period science has won or is winning many other victories as great. As regards tropical medicine, we have been advancing against plague, cholera, typhoid, sleeping-sickness, kala-azar, hook-worm, beri-beri, bilharzia, and leprosy; and as regards the diseases of temperate climates, we have diminished child-mortality, diphtheria, tuberculosis, numerous ailments due to local infections or to physiological insufficiencies, such as myxœdema, and, quite recently, have inflicted a defeat upon diabetes. We

[1] An address delivered to the Anderson College of Medicine, Glasgow, on October 9, at the opening of the winter session.

are getting on. How? By patient, obstinate, and ineluctable investigation—not in the fields of medicine only, but also in those of physics, chemistry, and zoology. Finally, it is just here that we have scored our greatest victory—against our own stupidity. We, or let us say the public outside these walls, are at last beginning to learn that investigation really matters: we are discovering discovery!

It was not always so, even among doctors. I remember a medical administrator saying, "I cannot keep a number of men idling about here with microscopes," and a High Commissioner exclaiming, "You say you do not know how to manage this outbreak! Surely you medical men *ought* to know." He seemed to think that all we had to do was to consult the Hippocratic Books. The idea that investigation is an essential part of practice has been of very slow growth. In India, when a European doctor was asked to cure a lady of the zenana, he was at one time not allowed to see her, and she was not permitted to do more than put out her tongue at him from behind a curtain. A distinguished English physician, who was, I believe, connected with my own family, is said to have deprecated all clinical examinations: we should know how to cure by instinct. To the public mind the physician loses caste by "wanting to know." He must practice, he may teach, but he should not require to investigate anything!

It has taken us centuries to free ourselves from the serpentine coils of this prejudice and to reach our present position—where investigation is the key-industry of all industries. The evolution of this revolution is interesting. The ancient Greeks certainly valued, not only practice and teaching, but also discoveries when made; yet we are not aware that they ever explicitly organised or encouraged research. Readers of the history of science often wonder how the old philosophers and geometers managed to live at all—probably by teaching and possibly on patronage or charity. They were private enthusiasts, and their fundamental discoveries do not appear to have been rewarded in any way. I am told that it is not known whether Plato demanded fees, as well as a knowledge of mathematics, for admission into his Academy; and the same may be said, I understand, regarding Aristotle's Lyceum. Several of the mathematicians, such as Eudoxus of Cnidos, appear also to have been practising physicians. It is to be presumed that the Museum at Alexandria was in essential particulars like a modern university, where teaching is the official duty of the staff, but where research and practice may be conducted at option between the lectures and classes, often with the assistance of students. We are told that after the collapse of the ancient empires and about the time of William the Conqueror, when Europe was plunged in darkness, the Arabs in Spain possessed a library of 600,000 volumes, an academy, and a fund for the endowment of learned men, probably employed for teaching.

Europe did not advance so far as this for centuries, but the monasteries maintained many learned monks, such as Roger Bacon, with whom the new dawn of science commenced. The great Italian anatomists of the sixteenth century were either practising physicians or members of universities. I think that the first real "research institute," subsidised by public and private funds for pure investigation only, was the famous Uraniborg of Tycho Brahe, founded in Denmark in 1576. It well subserved the proper purpose of such institutes, which is the collection of numerous and exact observations and measurements that are beyond the power of private investigators. Tycho Brahe brought no new integration into astronomy, and even opposed the fundamental theory of Copernicus; but his data enabled Kepler and Newton to revolutionise the science. It is interesting to note that Copernicus himself was only a "private enthusiast," a man of affairs, and a physician; and also that after twenty-one years the politicians stopped their subsidy for Uraniborg, as Mr. Alfred Noyes has described so pathetically in his fine epic of science, "The Torch Bearers." In those days the greatest men were often obliged to pick up a living as best they could—even by the use of alchemy and astrology. Kepler said sarcastically that "Mother Astronomy would surely starve but for the earnings of her daughter Astrology." Even in the observatories and museums which began to be founded after Uraniborg, official duties must have greatly interrupted investigation.

Thus we see that at all times, as often to-day, science has been compelled to get her living by more lucrative but less important pursuits, especially teaching and professional practice. Last century, however, the idea of special research institutes was taken up again with vigour, and the Pasteur Institute in Paris, the Jenner Institute in London, and a score or more similar foundations were established in most of the world's great cities, sometimes by private benefactions or bequests, sometimes by State subsidies, and often by both. Here we find a new principle at work—that of maintaining skilled investigators for research only, apart from teaching and practice. Allied to those, we now possess numbers of industrial research laboratories employed by commercial companies on the improvement of agriculture or of manufactures—and we know what America and Germany have done in this line. Then, again, our hospitals now possess laboratories both for clinical pathology and for research; while the professorial laboratories in all departments of science at our universities have been greatly enlarged and improved, though teaching is still, and quite properly, a part of their duties. Yet another advance is that of research scholarships, by which numbers of promising students are now employed for a few years on such investigations as attract them.

Lastly—and at very long last—the State itself has now joined in the pursuit of truth by means of large annual subsidies, such as those which are distributed in Great Britain by the Department of Scientific and Industrial Research and the Medical Research Council. It would be a difficult task to form even a rough estimate of the world's present expenditure on subsidised research. I think it must reach quite a million pounds a year. This is a small sum compared with the world's expenditure on armaments or education; but it is an improvement on the time when Socrates was obliged to argue in the market-place or Diogenes to fulminate psychoanalysis from a tub.

The improvement has been greatest in connexion with medical investigation. It was not so many years

ago that an American who had studied the matter told me that the world then possessed many fewer endowed professorships on pathology and hygiene than on Sanskrit, philosophy, and theology. This was rather surprising. Every one in the world is certain to suffer from some malady at least once; but no one need suffer from Sanskrit or philosophy unless he pleases, nor even from theology—during this life. But there has always been a thin vein of unreality in academic affairs. Now, however, even Sanskrit is beginning to pale before cancer. On the other hand, so recently as last June, I saw the announcement that the chief countries of the world contribute annually an average income of 9,594,254*l.* to the various Protestant Foreign Missions. This is nearly ten times the amount which I conjecture the world is now giving for the whole of its scientific investigations in all fields. North America gives to the Missions an average of 6,327,597*l.* a year and Great Britain gives 2,310,000*l.* a year; Germany has dropped out owing to the fall of the mark, but other countries contribute the balance. We are not jealous, but our mouths water at the thought of these vast sums. On one side, the missionaries, from your great *alumnus* David Livingstone onwards, have been the pioneers of civilisation and have done great work. On the other side, we think of the millions of people now dying prematurely every year of diseases which are probably easily curable or preventable, though we do not know how to cure or to prevent them at present.

On the whole, I think that the war-funds of science are likely to go on increasing year by year as the public becomes more and more convinced of results. The fundamental question is therefore now being asked, How best should we spend the money? Remember that, as I have shown, the endowment of investigation apart from teaching is only a recent innovation, and probably, like all new methods, has not yet been perfected. How can the best results be obtained for the least expenditure? The question must ultimately be decided by you young men: for us it remains only to attempt a preparatory analysis.

Regarding *medical* research there are two schools of opinion, which we may call the *Bulls* and the *Bears*. One school, the Bulls, say: "We must spend every penny we can raise on constant investigations managed by capable committees and carried on by trained research workers, maintained if possible for life in order to be sheltered from the necessity of teaching or practice, and provided with the most up-to-date laboratories, plenty of materials, and easy access to scientific literature. It is true that some money may thus be wasted, that some of the results may prove wrong, that some of the workers may not turn out so capable as they were thought to be: no matter. A single great success will be worth all the money that is likely to be spent in this way. Pour out the cash; catch all the young men you can and set them at their measurements and microscopes, and keep them at it as long as they are willing to stay. The larger the number of seekers the larger the number of finders. Drop the failures, cut the losses, and think only of the profits." To them the other party, the Bears, reply: "You can spend what money you like but you cannot buy discovery. All that your managing committees and trained investigators are likely to do or achieve will be the study of details along already well-trodden paths. They will inoculate legions of rats and guinea-pigs, and will publish profound but incomplete papers every quarter, which will be of little or no use in practice. They will carry out researches—yes, academic researches, and too many of them! But the world does not ask for researches; it asks for discoveries—not for the incomplete but for the complete article. Has a single great medical discovery been made by managing committees and subsidised investigators? Discoveries are made by genius—and that you cannot buy."

Such are the opinions which one hears on both sides. Personally I agree and yet disagree with both. There is only one way to decide. Research and discovery are themselves natural phenomena, and we should study them scientifically. I said we have discovered discovery: let us also investigate investigation. How? By consulting the great and triumphant history of science, particularly the stories of the chief advances. If we do so we shall see that the two parties are merely quarrelling over the two faces of the same coin. Science proceeds, not in one, but in two ways: first by collecting facts and then by basing inductions upon them. Thus, in the classical example already cited, it was Tycho Brahe who spent his life in collecting trustworthy observations regarding the positions of the heavenly bodies, but it was his pupil Kepler who, after twenty-five years' study of Brahe's figures, established the great induction that all the planets move in similar elliptical orbits round the sun; and it was Isaac Newton who, eighty years later, explained all these orbits by the single law of universal gravitation. That is, one man collected the facts, but other men explained them. For a second example: by the middle of last century numbers of workers, including Buffon and Linnæus and a host of private enthusiasts and amateurs, had observed, distinguished, and described innumerable kinds of plants and animals; then came Darwin, who explained these facts—much more numerous than he could ever have collected single-handed—by his theory of natural selection. For a third example: think of the host of physicians, surgeons, and apothecaries who have studied and described the characters and symptoms of human maladies without being able to explain them. Then came Semmelweiss, Pasteur, Lister, and Koch, who created bacteriology.

Certainly observation and induction have often worked together in the same research, with brilliant results. More often they pull different ways and break down. Every one knows the man who begins with his induction and then fits his facts to it—or thinks he does. On the other hand, the "working hypothesis" frequently suggests invaluable, though possibly negative, experiments. Then we have the men—generally young men—who make a new generalisation with every new observation: I was one of them once. Often, however, observation and induction require very different faculties, which belong to different men, often living in different ages. If we were all Newtons there would be no problems left to solve.

Science needs all the faculties—the eye of one man, the hand of another, and the brain of a third. Observa-

tion is at least as necessary to it as induction. Therefore I do not agree with the party of the Bears when they depreciate subsidised investigations carried out by full-time workers under managing committees. The present state of medical science requires constant physiological, pathological, therapeutic, and biochemical researches, often involving delicate measurements which cannot be made by medical practitioners outside laboratories, or even by teachers in the medical schools in their spare time. Spend therefore as much money as you can raise for this purpose; let every budding Pasteur have his chance; and pray for a Rockefeller. But at the same time considerable waste must be expected and allowed for. One does not envy committees of management. As Sir Ernest Rutherford recently said in his address to the British Association: "Those who have the responsibility of administering the grants in aid of research for both pure and applied science will need all their wisdom and experience to make a wise allocation of funds to secure the maximum of results for the minimum of expenditure. It is fatally easy to spend much money in a direct frontal attack on some technical problem of importance when the solution may depend on some addition to knowledge which can be gained in some other field of scientific inquiry, possibly at a trifling cost."

I can adduce many other difficulties. Workers are apt to be called away to other posts before their task is complete. Then who can know when an old vein is exhausted, or whether a proposed new line is really promising, unless he himself has worked at the job?—and few committees can consist of specialists in all possible lines. In my own subject I have known men employed who had never read the literature, who dug up again old disused workings, or who chased the wild goose with a pinch of salt for years—all costing money. But the greatest waste is caused by the large number of incomplete articles, constantly being published, which, though they may be good so far as they go, are lost in the mass of literature—so that when the man who clears up the question finally arrives he is obliged to rediscover all the matter for himself. But in spite of these difficulties I agree with the Bulls. The world must continue spending money in this way; and it will improve the system with practice.

Now for the other side—the obverse of the medal. One of our most distinguished physicians told me a few months ago that some one had accused him of not really being a man of science because he did not work in a laboratory! Yet he has made more valuable additions to medical knowledge and practice than has fallen to the lot of most laboratories. Consider this point carefully. The work of the laboratory has almost always been the collection of facts and measurements, the elaboration of detail, the testing of theories; but the other side of science, the great inductions which have solved problems or have applied facts directly to the cure or prevention of disease have been made mostly by that humble individual, the "private enthusiast"—generally either a teacher or a "mere doctor." William Harvey was a mere doctor; Edward Jenner, a mere country doctor! What laboratory did Jenner require? He did not even use a microscope, and yet he gave to humanity the greatest single boon which it has ever received, and also initiated our present knowledge of immunity. G. F. E. Küchenmeister, who first proved alternations of generations in parasites, was a practising doctor. Pasteur was a professor of chemistry. Lister was a practising surgeon in Glasgow. Robert Koch was also a mere practising country doctor when he discovered the bacilli of anthrax and of surgical sepsis, the staining of bacteria, and plate-cultivation, thus making practical bacteriology. Manson was a doctor in China. Laveran, Bruce, Reed, and Leishman were or are army doctors. Need I mention any more names?—I should have to hurl almost the whole history of medicine at you! Where were the laboratories of these men?—in their own hospitals and consulting-rooms. Where were the laboratories of Kepler and Newton?—in their own brains. Who are making the innumerable advances which we see to-day in connexion with medical, surgical, and sanitary practice regarding almost all diseases? Very largely our professors, our teachers, our laboratory workers, it is true; but also, and not less, our clinicians and our hygienists.

We see then that there is much to be said for the Bears as well as for the Bulls. It is an historical fact that most of the greatest advances have been made by men who were not subsidised for their researches. I think, therefore, that the whole field of public support for science should be broadened so as to include such men. At present the public gives considerable sums for institutional investigations with the test-tube, the scalpel, and the microscope, but little or nothing for workers outside. That is, it supports, and rightly supports, observational science, which is largely ancillary, but scarcely helps those great intellectual investigations which mostly obtain the final or useful results. It would have subsidised Tycho Brahe's observatory at Uraniborg; but it would probably have refused a penny to Kepler, or to Newton, or to Jenner. It pays for digging the foundations of the Temple of Medical Science, but leaves the building of the walls and towers to the practitioner and the enthusiast—often at their own cost. It pours out money for the expectation of discoveries to come, but refuses to give anything for discoveries already completed by private individuals!

It seems to me that all this is very "bad business." We should pay not only for expectations but also for results. I should like to see the whole medical profession brought into the research fold—not in laboratories, but in their practice, their consulting-rooms, and their own brains. Some one will say that the private enthusiast will continue to work whether we help him or not—surely the meanest argument ever used!—but will he? Then some one else will exclaim that there is nothing to hinder any and every medical man from investigation. I am not so sure. True, hundreds or thousands of them are now actually thus engaged, and, in fact, are obtaining the important results just mentioned; but large numbers of medical men cannot always afford such a luxury, because they have to maintain their practices. The reason for this is that while clinical researches which improve medical and surgical treatment often *enhance* practice—and very deservedly so—other scientific work, such as physiological and pathological studies, which are off

the main lines of clinical research, often notoriously *injure* practice. There is still a feeling that a man will not be "a good doctor" if he takes to flying the scientific kite too often. Thus every one knows that both Harvey and Jenner ruined their respective practices by their scientific studies. For another example, it was said of Thomas Young, the father of physiological optics and discoverer of many great theorems on light, heat, and energy, that he "was not regarded as a successful practitioner, because he studied symptoms too closely, although his treatment was admitted to be effective." In other words, he cured his cases by studying their symptoms instead of studying the correct bed-side manner! Wise or not, this feeling has to be considered by practical men. Then there is a third class of effort—perhaps the very highest class of medical work—which is concerned with the prevention of the great epidemic diseases. At present it receives no payment whatever, either from practice or otherwise. What has been done, for example, for Mr. W. M. M. Haffkine or for Mr. H. E. Hankin—both laymen and private enthusiasts—whose studies have saved untold numbers of lives from cholera and plague in India and elsewhere; or for the almost unknown doctors who discovered that plague—the world-destroying plague—is carried by the rat-flea?

Such drawbacks, and others, are unfortunate, because they tend to impede enlistments in the great voluntary army of medical science. Our friend the private enthusiast is a rare species; and the successful enthusiast is very rare indeed. You cannot subsidise him beforehand, because you cannot discover him until he has *done his work*. You can supply him with laboratories, test-tubes, and microscopes—if he wants them, but you cannot pay him for his thoughts, his calculations, or his natural aptitude, nor, above all, for that passion for discovery—for discovery not merely for investigation—which drives him over every obstacle to his ultimate goal. You cannot subsidise him, and you cannot reward him either. It is beyond the power of the whole earth to reward him; his discovery is his reward. But still you can do something for him in a small way. In 1802 and 1807 Parliament compensated Jenner for the loss of his practice; in 1884 the German government did the same for Robert Koch; and quite recently, I understand, the Canadian government has, very wisely, shown the same consideration to Dr. Banting for his brilliant labours on insulin.

The *least* that the world can do for the successful investigator, whomsoever he may be, is to pay honourably such of his little out-of-pocket expenses and losses as he may have incurred in the world's service; and the *most* that the world can do for him is—to keep him at work. This is the way in which money can now be most profitably spent for science. I see that Sir Alfred Yarrow has recently given a fine donation, which is to be devoted partly to this purpose. If I were a millionaire I should follow his example.

It is often said that there is no such thing as discovery, that each advance is built upon previous advances. True; but what is the interval between these advances? Many people carry on incomplete investigations, and just miss their triumphant culmination. The culmination is the discovery. I have often wondered how it was that those wonderful people, the ancient Greeks, missed four great discoveries which they seem to have been on the point of achieving—the calculus, evolution, electricity, and vaccination. As it is, the world was obliged to wait for nearly two thousand years before these little "advances" were made. It awaited the proper men. Only the other day an able biochemist told me that probably most of the facts regarding the complicated diseases of metabolism are already known, but that another Newton is required to integrate them. Such, I think, may also be the case regarding other grave medical problems, as, for example, that of cancer. Possibly the discovery may already be made, but there is no one to drag it forth into the light. In science, as in art, the man is everything.

I must make one more remark. What always amazes me is the fact that there are millions upon millions of human beings whose health and whose very existences are constantly threatened by numbers of diseases, and yet who never subscribe one farthing for the medical researches which endeavour to defeat these terrible enemies of theirs, and often succeed in doing so. Yet thousands of these same people pour out their subscriptions and bequests for all kinds of projects, many of which are futile; while even those good and generous people who maintain our hospitals and universities seem often to forget that behind hospital practice and behind university teaching there is th great science which inspires both.

I have tried to give you a brief review of what may be called the natural history of discovery. "The management of medical research" will lie in the hands of you young people; but you must study the book of the past in order to direct the advances of the future. I hope that most of you will be "mere practising doctors"; but, if so, let every afferent and efferent nerve of your thoughts connect the brain of science with every sense, muscle, and faculty of your practice. The practitioner nowadays cannot live apart from science, trying to evolve wisdom from his own meditations, like a hermit in the desert: you must not only observe, but also think; and not only think, but also read. Your first duty will be the cure or prevention of sickness; but some of you in your leisure may perhaps try to solve problems, may become enthusiasts, may even become wild enthusiasts!—I cannot imagine a nobler fate. Even, perhaps, one of you—probably not more—may be destined to become the Newton or Einstein of some hitherto undreamed-of synthesis. I hope so.

Science has indeed measured the stars and the atoms, has knit together the corners of the earth, and has enabled us to fly over oceans and deserts; but her greatest victory remains to be won. Why should we men, heirs of all the ages, continue to suffer from such mean things as diseases? Are you going to be defeated any longer by bacilli, rat-fleas, and mosquitoes? It is for you to conquer them; and remember that every gift of science is a gift not to one country or to two countries, not only for to-day or for to-morrow, but also to the whole world and for all time, until, as the poet said,

"The future dares forget the past."

The Recent Eruption of Etna.

By Prof. GAETANO PONTE, of the Etna Vulcanological Institute.

DURING the last ten years Etna has exhibited various phenomena of considerable interest, especially at the lateral crater which appeared in May 1911 on the north-eastern slope of the central cone at the 3100 metre contour. This was the forerunner of a more violent eruption in September of 1911, when the new north-east crater became more active than the central one.

In 1917 a luminous column rose like a fountain a thousand metres above the north-east crater, and about 50,000 cubic metres of very fluid lava were poured out in about half an hour, without either rumblings or shakings of the ground. This afforded most striking proof of the resistance of the structure of the volcano to the enormous forces propelling the lava, which was raised not by the force of volcanic gases, but by powerful static pressure.

In June 1922 the activity of the north-east crater was resumed, and there were feeble explosions. In the spring of 1923 its activity increased still more, and at the foot of the explosion-cone which had been formed, some streams of lava appeared and spread out in short many-branched flows over the snow-fields. It was very interesting to observe the phenomenon of the hot lava spreading over the snow without melting it, but rather transforming it into ice under the weight.

The activity of the north-east crater continued until the outbreak of the eccentric eruption, which was preceded by the great explosions in the central crater, where, on June 6 last, the throat of the volcano, obstructed since 1918, reopened and ejected gigantic pine-tree clouds of reddish ash to a great height above the crater.

Following this the sky remained obscured for many days, and observations became impossible. At 2.30 A.M. of June 17 the inhabitants of the northern slope of the volcano were rudely awakened by deep rumblings and shakings of the ground, while near the craters of 1809, at the 1500 metre altitude, there rose imposing outpourings of lava; meanwhile other craters opened and other streams ran lower down the mountain, until at 4 A.M., at the 2000 m. contour on the western slope of Monte Ponte di Ferro, and at the south-western foot of Monte Nero, there were established definitely the craters of the main flow. The flow of Monte Nero, which was feeble and of short duration, ran over the bed of the 1879 lava for about 3 kilometres, but the mouth from which it flowed closed on June 21, whereas the flow from Monte Ponte di Ferro, which was of much greater extent, invaded the pine-forest of Petarrone, and, rapidly running down the eastern side of the lava-flow of 1911, reached in a few hours the Piano dei Filici, where, spreading its front, it headed towards Cerro and destroyed the vineyards and the nut-plantations of the Piano di Pallamelata (see Fig. 1).

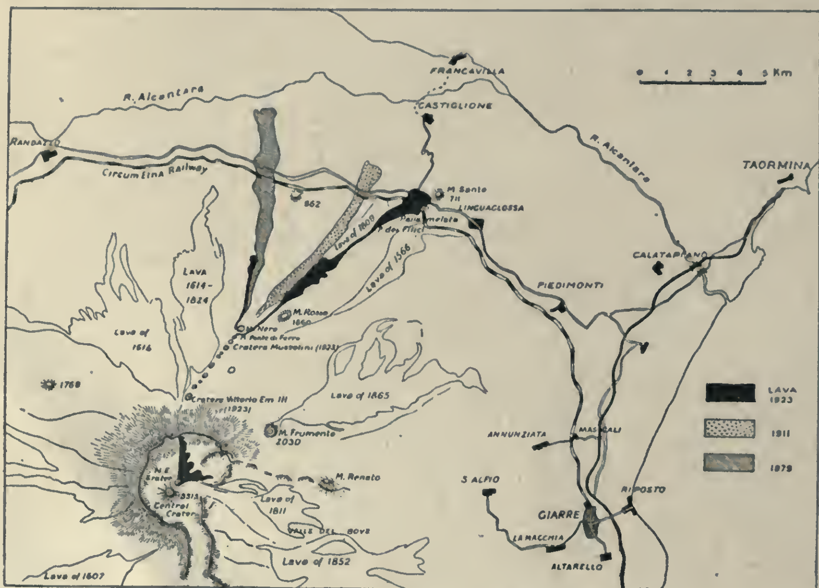

FIG. 1.—Sketch-map of north-eastern part of Etna, showing track of lava.

In ten hours the lava had travelled about 7 kilometres, falling in that distance 1200 metres, but as soon as it reached the plain, as has happened in other eruptions of Etna, it slackened the speed of its advance, spread fan-wise, and swelled like the carapace of a tortoise. Thus it happened that the front of the lava, which on the evening of June 17 was about 1 kilometre from the Circum-Etna Railway, reduced its speed, and did not invade the station of Castiglione until the night of June 19.

On June 20, when the King of Italy arrived in the region devastated by the lava-flow, the front was already 1 kilometre in width, and was still advancing at a speed of from 10 to 15 metres per hour. On the following day, when the Premier, Signor Mussolini, arrived, the flow had reached the foot of Monte Santo and continued to spread out slowly like a fan, enveloping the last few houses of the Catena suburb and threatening the town of Linguaglossa. Fortunately, however, from that day the impetus of the lava began slowly to diminish, and by June 26 its rate of advance was reduced by a half. The front of the lava-flow, not being sufficiently fed from its source, stopped definitely on June 29, but on the Piano di Pallamelata, on the eastern side of the flow, a fresh branch was formed, which at first threatened to give a new direction to the devastating torrent. In the meantime, higher up on the lava-flow there were further additions and lateral outbreaks. At some points the crust of lava

formed blisters, some of which, becoming solidified and remaining hollow, finally crashed in, owing to the lateral fissures. The emission of lava continued slowly until July 18, when the fiery torrent appeared to have solidified in the crater-mouth. The area covered by the lava is about three square kilometres, as estimated from the photographs taken by me from the hydroplane M. 28, kindly placed at my disposal by Signor Mussolini.

From the phenomena observed during the eruption, it can be seen that its progress was in direct relation to the mass of the lava emitted, and the various incidents were the consequences of special local conditions. If the structure of Etna were homogeneous, that is to say without hollows or fissures, the molten lava would not have departed from its principal eruptive conduit, and the eruption would have developed in the central crater. The passages which abound in the lava-flows on the slope of the volcano represent, however, so many subterranean routes which the molten lava could follow through a breach in the principal conduit, which might be formed by the simple collapse of weak parts of its walls or by breaking through where the rock was corroded by acid vapours. We do not know the changes that may have taken place along the epi-subterranean canal during the present eruption, but if its main vent near the principal eruptive conduit is still open, we can assume that with any renewed rise of the magma the lava will follow the same route. If, on the other hand, the breaches in the main pipe have been closed, the magma will reappear at the central crater until other subterranean routes are opened.

It is not possible to give a more explicit explanation of the eruption of Etna. The hypothesis of radial fractures which split the volcano at its base is not in harmony with the observed phenomena, and is contrary to the principles of the statics of liquids.

In this eruption it has been observed that the explosions were due to the detonation of explosive mixtures of volcanic gases—hydrogen, carbonic oxide, and methane—which are given off by the lava, and, when collected in subterranean cavities, form explosive mixtures with the oxygen of the air. The explosions were strongest in those parts of the fissures where deep chambers had formed in which the gases could collect, while towards the uncovered portions of the lava-canal there were milder explosions, with only small jets of lava. Later, when along this canal small cones were formed with corresponding explosion-chambers, the noises became intense. At the mouths of some of these small explosion-cones, there were often seen hissing darts of flame like those of powerful oxyhydrogen jets. These flames, due to the burning of the volcanic gases, have been observed at other volcanoes.

Various experiments were made during this important eruption. Of particular interest were the successful attempts to reduce, or even to stop for a short time, the explosions at some of the craters near their mouths by introducing carbon dioxide gas, which prevented the combustible gases from meeting with the oxygen of the air. In another experiment, nitrogen was blown through the liquid lava in order to carry away the gases given off, and to enable them to be collected without contamination by the air. This was carried out by means of a special apparatus, already described in the *Rendiconti della Reale Accademia dei Lincei*, vol. xxxi.,

[*Photo: G. Ponte.*

FIG. 2.—The north-east crater at the beginning of the eruption of May 1923.

1922, pp. 387-389. From the repeated trials made, it was definitely proved that the gases so collected are free from water. Thus the theory of the anhydrous nature of the magmatic gases, advanced by Albert Brun, receives fresh experimental confirmation.

on the cyclonic movements caused by convection currents in the hot air over the lava-flow.

In honour of the King and the Premier, the Accademia Gioenia di Catania has given the name Vittorio Emanuele III. to the new craters in the upper part of

[Photo: G. Ponte.

Fig. 3.—Explosion-craters, Vittorio Emanuele III.

Many observations were made of the temperature of the lava, and it was found that this varied in different parts of the flow owing to superficial cooling in contact with the air. At a temperature of from 670° to 690° the lava was still pliable, and could be easily bent and compressed. Some interesting observations were made the eruptive region, and has named those near the vent from which the lava issued Crateri Mussolini.

Many foreign vulcanologists came to see the eruption, and among them I had the pleasure of seeing Dr. G. Kemmerling, chief of the Vulcanological Service of the Dutch Indies.

Population and Unemployment.[1]

By Sir William H. Beveridge, K.C.B.

The impression that the civilised world is already threatened with over-population is very common to-day. Many, perhaps most, educated people are troubled by fear that the limits of population, probably in Europe and certainly in Great Britain, have been reached, and that a reduction in the rate of increase is an urgent necessity. Most, if they were asked to give reasons for their fear, would refer to one or both of two reasons: they would point to the enormous volume of unemployment in Britain; they would say that economic science, at least at Cambridge, had already pronounced its verdict. I propose to begin by raising some doubts as to the validity of each of these arguments.

The volume of unemployment in Britain is undoubtedly serious, and almost certainly unparalleled in past history. Those who see, as we now do, more than a million wage-earners whom our industry for years together is unable to absorb in productive employment may be excused if they draw the inference that there are too many wage-earners in the country. The inference, though natural, is unjustified. Unemployment in Britain can in any case prove nothing about the world as a whole. History shows that it does not prove over-population even in Britain.

During the last half of the nineteenth century, the industry of the United Kingdom was finding room for a rapidly increasing number of wage-earners with an admittedly rising standard of production and comfort. Through the whole of that period there was unemployment in the country. The percentage of trade unionists out of work never fell to zero; in no year since 1874 was it less than two; at more than one crisis it reached a height comparable if not equal to that which we have

[1] From the presidential address delivered to Section F (Economic Science and Statistics) of the British Association at Liverpool on September 17.

just experienced. During 1922 this percentage has averaged fifteen; but it averaged over eleven in 1879 and over ten in 1886. These figures are not on an identical basis, and are therefore not absolutely comparable. Taken for one year only, they understate the relatively greater seriousness of our recent experience, since the unemployment percentage was high through a large part of 1921 as well as in 1922, and still continues high. But the difference is one of degree rather than of kind. The peril of inferring over-population from unemployment is conclusively shown.

The experience of 1879 was up to then unparalleled; probably it was as much worse than anything previously recorded as the experience of 1922 appears worse than that of 1879. The experience of 1879, however, the record year of unemployment, heralded, not over-population and the downfall of British industry, but a period of expansion and prosperity which reached, if it did not pass, all previous records. "Real wages," which had risen thirty per cent. in the twenty years to 1880, rose even more rapidly in the next twenty years to 1900. Any one who in 1879, looking at the half or three-quarter million unemployed, had argued that the existing population of the United Kingdom (then about thirty-four millions) was all that the country could support without lowering its standards, would have been lamentably discredited at once. Ten years later he would have found a population nearly three millions more, enjoying a real income per head that was a fifth greater, with the unemployment percentage reduced to two. Ten years later still the population had grown further in size and in prosperity; those trades had grown most rapidly in which there had been and continued to be the largest percentages of unemployment.

The problems of unemployment and of over-population are distinct; they are two problems, not one. Severe unemployment has occurred in the past without over-population, as a function of the organisation and methods of industry, not of its size. On the other hand, it is very doubtful if excessive growth of population has ever shown itself or would naturally show itself by causing unemployment. A more probable effect would be pressure to work more than before in order to obtain the same comforts: a fall of real wages per hour, by increase either of hours or of prices.

The same dependence of unemployment on the organisation and methods of industry, rather than on its size, appears if we look, not backwards in time, but round us in space. It has been pointed out by Prof. Cannan that one of the few groups of economists who from our post-War sufferings can at least obtain the high intellectual satisfaction of saying "I told you so," is that which maintains that changes in the purchasing power of money are the most potent causes of the fluctuations in prosperity known as cycles of trade or booms and depressions. "In the pre-War period booms and depressions swept over the whole western world at once and left their causes obscure. In 1922 we have been treated to a sharp contrast between two groups of countries, one group having boom and full employment, the other depression and unemployment, the difference being quite clearly due to the first group having continued the process of currency inflation, the other group having dropped it." To bring this generalisation down to particular examples, we see in Central Europe a nation which assuredly should be suffering from over-population if any nation is; Germany, defeated in war, has been compressed within narrower limits, has lost its shipping and foreign investments, its outlets for emigration and trade, and now by high birth-rates is repairing with exceptional speed the human losses of the War. Germany may or may not be suffering from over-population. She certainly has not suffered from unemployment; she has had a boom stimulated by inflation of the currency. We see on the other hand Britain, victorious in war, with expanded territories and the world open to her, pursuing a different, no doubt a better, currency policy, and experiencing unexampled unemployment. To argue uncritically from unemployment to over-population is to ignore the elements of both problems.

. . . .

In regard to Europe as a whole we find no ground for Malthusian pessimism, no shadow of over-population before the War. Still less do we find them if we widen our view to embrace the world of white men. The fears expressed by Mr. Keynes in his book "Economic Consequences of Peace" seem not merely unnecessary but baseless; his specific statements are inconsistent with facts. Europe on the eve of war was not threatened with a falling standard of life because Nature's response to further increase in population was diminishing. It was not diminishing; it was increasing. Europe on the eve of war was not threatened with hunger by a rising real cost of corn; the real cost of corn was not rising; it was falling.

. . . .

For Europe and its races the underlying influences in economics were probably still favourable when the War began. But the war damage was great, and we are not in sight of its end. Man for his present troubles has to accuse neither the niggardliness of Nature nor his own instinct of reproduction, but other instincts as primitive and, in excess, as fatal to Utopian dreams. He has to find the remedy elsewhere than in birth control.

Let me add one word of warning before I finish. Such examination as I have been able to make of economic tendencies before the War yields no ground for alarm as to the immediate future of mankind, no justification for Malthusian panic. It has seemed important to emphasise this, so that false diagnosis should not lead to wrong remedies for the world's sickness to-day. But the last thing I wish is to over-emphasise points of disagreement with Mr. Keynes. The limits of disagreement are really narrow. The phrases that I have criticised are not essential to Mr. Keynes's main argument as to the consequences of the War and the peace. Whether Mr. Keynes is right or, as I think, too pessimistic as to economic tendencies before the War, he will, I am sure, be regarded as right in directing attention again to the importance of the problem of population. Nothing that I have said above discredits the fundamental principle of Malthus, reinforced as it can be by the teachings of modern science. The idea that mankind, while reducing indefinitely the risks to human life, can, without disaster, continue to exercise to the full a power of reproduction adapted to the perils of savage or pre-human days, can control death by art and leave

births to Nature, is biologically absurd. The rapid cumulative increase following on any practical application of this idea would within measurable time make civilisation impossible in this or any other planet.

In fact, this idea is no more a fundamental part of human thought than is the doctrine of *laissez faire* in economics, which has been its contemporary, alike in dominance and in decay. Sociology and history show that man has scarcely ever acted on this idea; at nearly all stages of his development he has, directly or indirectly, limited the number of his descendants. Vital statistics show that the European races, after a phase of headlong increase, are returning to restriction. The revolutionary fall of fertility among these races within the past fifty years, while it has some mysterious features, is due in the main to practices as deliberate as infanticide. The questions now facing us are how far the fall will go; whether it will bring about a stationary white population after or long before the white man's world is full; how the varying incidence of restriction among different social classes or creeds will affect the stock; how far the unequal adoption of birth control by different races will leave one race at the mercy of another's growing numbers, or drive it to armaments and perpetual aggression in self-defence.

To answer these questions is beyond my scope. The purpose of my paper is rather to give reasons for suspending judgment until we know more. The authority of economic science cannot be invoked for the intensification of these practices as a measure for to-day. Increased birth control is not required by anything in the condition of Europe before the War, and is irrelevant to our present troubles. But behind these troubles the problem of numbers waits—the last inexorable riddle for mankind. To multiply the people and not increase the joy is the most dismal end that can be set for human striving. If we desire another end than that, we should not burk discussion of the means. However the matter be judged, there is full time for inquiry, before fecundity destroys us, but inquiry and frank discussion there must be.

Two inquiries in particular it seems well to suggest at once. The first is an investigation into the potential agricultural resources of the world. There has been more than one elaborate examination of coal supplies; we have estimates of the total stock of coal down to various depths in Britain and Germany, in America, China, and elsewhere; we can form some impression of how long at given rates of consumption each of those stocks will last; we know that "exhaustion" is not an issue for this generation or many generations to come. There has been no corresponding study of agricultural resources; there is not material even for a guess at what proportion of the vast regions—in Canada, Siberia, South America, Africa, Australia—now used for no productive purpose, could be made productive; and what proportion of all the "productive" but ill-cultivated land could with varying degrees of trouble be fitted for corn and pasture. Without some estimate on such points, discussion of the problem of world population is mere groping in the dark. The inquiry itself is one that by an adequate combination of experts in geographic and economic science—not by a commission gathering opinions or an office gathering statistical returns—it should not be difficult to make.

The second is an investigation into the physical, psychological, and social effects of that restriction of fertility which has now become a leading feature of the problem. This also is a matter neither for one person —for its scope covers several sciences—nor for a commission; facts rather than opinions or prejudices are required.

If the question be asked, not what inquiries should be made but what action should now be taken, it is difficult to go beyond the trite generalities of reconstruction, of peace and trade abroad, of efficiency and education at home. The more completely we can restore the economic system under which our people grew, the sooner shall we absorb them again in productive labour. Unless we can make the world again a vast co-operative commonwealth of trade, we shall not find it spacious enough or rich enough to demand from Great Britain the special services by which alone it can sustain our teeming population. Even if the world becomes again large enough to hold us, we shall not keep our place in it with the ease of Victorian days; we dare no longer allow, on either side of the wage bargain, methods which waste machinery or brains or labour. Finally, if there be any question of numbers, if there be any risk that our people may grow too many, the last folly that we can afford is to lower their quality and go back in measures of health or education. Recoil from standards once reached is the gesture of a community touched by decay.

Obituary.

Mr. Frederick Chambers.

THE death is announced of Mr. Frederick Chambers, late Meteorological Reporter for Western India, at the age of seventy-seven years. Mr. Chambers was the younger brother of Charles Chambers, who went out from Kew Observatory in 1864 to take charge of the Colaba Observatory, Bombay. Frederick went out as assistant to his brother. In 1873 his paper, "The Diurnal Variation of the Wind and Barometric Pressure at Bombay," was published in the Phil. Trans. of the Royal Society, and another paper, "Mathematical Expression of Observations of Complex Periodical Phenomena; Planetary Influence on the Earth's Magnetism," written in collaboration with his brother, appeared in the Phil. Trans. in 1875. About this time Mr. Chambers was appointed Meteorological Reporter for Western India. A quotation from the first annual report which he printed is not without interest. It is explained that meteorological instruments had been sent out from England in 1852, "the duty of making the observations at those places being imposed on the senior medical officers"; the comment is made, "We would hope that from the zeal and energy of medical officers in charge of European hospitals and their love of science, the observations may be made by themselves and their establishments,

without entailing on the public any expense on this account."

The zeal and energy of the medical officers, and their love of science, however, seem not to have been equal to the occasion, for after vainly endeavouring, until the end of 1855, to carry out the orders they had received, without entailing expense on the public, it was arranged, at the direction of the Honourable Board, that two European soldiers should be told off at each station to undertake the duty of making meteorological observations on an allowance of 25 rupees per month for each observatory. The soldiers were sent to the Bombay Observatory early in 1856 for a preparatory course of training, on the successful completion of which they were furnished with certificates of competency to perform the work. Soon after this time the real work of meteorological registration may be said to have commenced, for, so far as the observers are concerned, the work from this time appears to have been carried on generally in a thorough and satisfactory manner. Under Mr. Chambers's administration the instruments were for the first time regularly compared with standards, and trustworthy data, such as made the Climatological Atlas of India possible, were collected.

Dr. Christian Hess.

One of the directors of the Farbenfabriken vorm. Friedr. Bayer und Co., in Leverkusen, Dr. Christian Hess, died on July 11 in Bonn, after a serious operation. He was born January 14, 1859, at Eisenach, studied chemistry first at Jena and then in Berlin, where he worked for his doctorate under A. W. v. Hofmann in 1881. After having been assistant chemist to Prof. Wichelhaus at the Institute of Chemical Technology, he went in 1883 to the newly founded weaving, dyeing, and finishing school in Crefeld, where he developed very great activity as a teacher and an expert adviser. At that time he invented his process for removing iron from water. The large number of coal-tar dyestuffs of a new character, which were discovered at that time, brought with them the necessity of using new methods for dyeing. This caused a lot of difficulties in the dyeworks, to meet which the dyemakers engaged colourists of good chemical training, able to introduce the new methods. One of the first of these was Dr. Hess, who was engaged by the Farbenfabriken in 1894.

Dr. Hess showed remarkable commercial ability, and after some time the whole of the sale of dyestuffs was entrusted to him; he was nominated a director in 1906. His knowledge of men and things enabled him to render many important and lasting services to the industrial side. His firm, his colleagues, his employees and the great number of men he helped with good advice, with sound reasoning and with hearty encouragement, when in difficulties, will much regret his premature death.

Prof. J. Violle.

The issue of the *Revue scientifique* for September 22 contains a notice of the death of Jules Violle, professor of physics at the Conservatoire des Arts et Métiers, which occurred at Fixin, near Dijon, on September 12. Violle was born in the same district on November 16, 1841. After obtaining his doctorate in 1870, he was in succession professor of physics at Grenoble, at Lyons, and at the École Normale. In 1897 he was elected a member of the Paris Academy of Sciences in succession to Fizeau. He was president of the French Physical Society, of the Society of Electricians and of the Committee of Inventions for National Defence. His earliest research was a determination of the mechanical equivalent of heat by means of the Foucault currents in a disc rotating in a magnetic field. His result, about 4 per cent. too high, was published in 1870. His work on the temperature of the sun appeared in 1877, and in 1884 he proposed as a standard of light, that radiated normally by a sq. cm. of molten platinum at its freezing-point. From 1886 to 1905 he published in conjunction with Vautier a number of memoirs on the speed of sound particularly in tubes. His "Cours de physique," which began to appear in 1883, was never completed.

We regret to record the death, on July 26, of Alexander Ellinger, professor of pharmacology in the University of Frankfort. Before the foundation of the latter university Ellinger held a similar chair at Königsberg. He was best known for his chemical work. Thus he showed that ornithine and lysine are decarboxylated by bacteria to putrescine and cadaverine respectively. He supplied the final touches to the determination of the constitution of tryptophane, and synthesised this amino-acid. Its transformation to kynurenic acid by the animal organism occupied much of his attention, and a few years ago he was able to elucidate the mechanism of this peculiar change, which apparently takes place via the keto-acid corresponding to tryptophane.

The Brooklyn Museum Quarterly of July includes an obituary notice of Prof. William Henry Goodyear, best known by his work entitled "The Grammar of the Lotus," who died in February last aged seventy-seven. The theory developed in this book was conceived during his studies of lotiform decorations in Cypriote art, and included a study of the lotus in the decorations on peat from early Egyptian times. In his work as an architect his discoveries of architectural refinements will prove most important. His published work is extensive and valuable, and is fully recorded in the sketch of his career by Mr. W. S. Conrow.

We regret to announce the following deaths:

Sir Halliday Croom, emeritus professor of midwifery at the University of Edinburgh and lately president of the Royal College of Surgeons, Edinburgh, on September 27, aged seventy-six.

Dr. P. Friedländer, professor of organic chemistry and of organic-chemical technology at the Darmstadt Technical College, aged sixty-six.

Dr. Herbert McLeod, F.R.S., honorary director of the Royal Society Catalogue of Scientific Papers, on October 1, aged eighty-two.

Current Topics and Events.

PROF. LYDE's leading article in last week's NATURE points to the need for a scientific basis for any programme aiming at the development of Empire resources which may result from the deliberations of the Imperial Economic Conference. A satisfactory organisation for effecting this purpose should embrace three main lines of work, namely, the exhibition of Empire raw materials, the technical examination of "new" or little-known products, and the systematic collection and dissemination of information relating to raw materials, their marketing and industrial use. An organisation originally designed for the purpose exists in the Imperial Institute. The Public Exhibition Galleries provide what is unobtainable elsewhere, namely, a permanent exhibition, under one roof, of the resources of all the countries of the Empire, so organised that a visitor desiring special information is, on inquiry, referred to the appropriate department of the Institute. These collections should be of great value to the business man, and their educational importance to the university student, no less than to the scholars who visit the Galleries in large numbers, conducted by the official guide, is obvious. Special lectures for the general public are also given by recognised authorities. The complement of the collections is the Scientific and Technical Department, the investigations of which—specially planned to meet the needs of the case—in conjunction with the assistance of the technical and commercial committees of the Institute, have served the economic development of the Empire to a degree unsuspected by the general public. The essential link in the scheme, namely, the collection and dissemination of technical and other information, and an organisation for dealing with the constantly growing stream of inquiries, exists in the Technical Information Bureau, which forms the intelligence department of the Institute and has proved of great practical service.

OUR famous medical contemporary, the *Lancet*, began its hundred and first year of publication on October 6, when a supplement was issued of nearly eighty pages, profusely illustrated by the portraits of many distinguished friends and some of the equally distinguished enemies of the paper. The text, modestly and humorously written, is a truly remarkable record of facts in medical highways and byeways during the past century. It is not too much to say that the present state of medical education and practice in England, its established efficiency and security and freedom from all grave abuses, is as much due to Thomas Wakley's *Lancet* as to anything else. Its scurrilities, venomous nick-names—"little eminent"—the rollicking old libels, semi-caricatures, "intercepted letters," and grandiloquent but downright abuse in plain English are now things past regret. Wakley's handling of them was perfectly in accord with his time; while his sense of right, his courage, and his devotion to a great cause would receive high admiration in our own. In the first ten years of his paper's existence there were six actions for libel, the aggregate sum of 8000*l*. being claimed for damages; the aggregate of 155*l*. 0*s*. 0½*d*. was awarded, the editor's costs being largely defrayed by public subscription. The design of the paper was to supply medical information which was available at that time to but few people, and to show that hospitals were not served, and that students were not trained, by persons selected for their merits. The libel actions arose out of the publication of supporting evidence, and ceased as reforms followed. Wakley's accusations of nepotism in hospital management and malpraxis in hospital practice gained public hearing in the Bransby Cooper case. His campaign against the Royal College of Surgeons of England, at first mismanaged, resulted in the appointment, in 1834, of Warburton's Parliamentary Committee of Inquiry into the state of the medical profession, and, later, in the Act constituting the General Council. Since then, lunacy, food adulteration and water-supply, workhouse administration, the advancement of Lister's views and of anæsthetic technique, and, indeed, every notable contribution by science to medicine, have in turn provided the *Lancet*, under Wakley guidance, with fields for great constructive work. The Centenary Supplement is a document of absorbing interest, personal and professional, a becoming memorial to great Englishmen.

MR. W. J. U. WOOLCOCK, the General Manager of the Association of British Chemical Manufacturers, described to representatives of various technical journals on Monday last the progress which has been made with the preparation of the Chemical Section of the British Empire Exhibition to be held at Wembley next year. The Chemical Section, which is being organised by the Association, and occupies nearly 40,000 square feet in the Palace of Industry, will be built in such a way as to form a Hall within the Palace. About 100,000*l*. will be spent in presenting to the public a picture of the present state of British chemical industry. No important firm in the industry will be unrepresented, and the whole of the individual exhibits, numbering about one hundred, will, by reason of their position and character, combine to form a magnificent illustration of the industry. Considerable attention has been paid to the lay-out and to the decoration of the Chemical Hall. There will, for example, be about two hundred yards of a specially painted frieze illustrating various operations in chemical manufacture; and as the majority of the stands are being designed by the same architect, the treatment of each stand is likely, while maintaining the individuality of the occupier, to present a very pleasing picture of the Hall as a whole. In the centre of the Chemical Hall there is to be illustrated the progress which has been made in pure chemistry during the past twenty or thirty years, with the view of showing that the stream of scientific invention in this country is still flowing steadily onwards. The Scientific Section is being organised by a Committee consisting of representatives of the following bodies: The Chemical Society, the Institute of Chemistry, the Societies of Chemical

Industry and of Dyers and Colourists, the Pharmaceutical Society, and the Institutions of Petroleum Technologists and Chemical Engineers. The Committee is working in close co-operation with the Royal Society. Sir Herbert Jackson acts as the representative of the Royal Society on the Committee and Mr. Woolcock in a similar capacity on the Royal Society Committee. In order that both the general public and scientific persons may have a record of the exhibit, it is proposed to publish a number of pamphlets specially written for the purpose dealing in popular language with the various classes of exhibits in the Scientific Section. In addition to this it is proposed to publish in more technical language a work, which will not only explain the scientific exhibits, but will put on record in a very complete form the state of our knowledge in chemical matters at the date of the Exhibition. It is anticipated that there will be a very large demand for this valuable record, each chapter of which will be contributed by an authority in the subjects dealt with, and that it is likely to find a place on the bookshelf of every scientific worker.

IN the hope of checking the rabbit pest in Australia, it is proposed by the Commonwealth to make large advances, not exceeding 250,000*l.*, to cover the cost of supplying settlers with wire netting on easy terms. Every State would get a fair proportion of the netting. The second reading of the bill has been carried in the House of Representatives. The money is to come out of the Consolidated Revenue Fund, and its amount indicates the continued seriousness of the situation. In the course of the discussion in the House it was mentioned that thousands of acres, in South Australia in particular, had depreciated to half their value owing to the rabbit pest, and it was stated that whereas in 1893 there were 60,000,000 sheep in New South Wales, the number was now down to 32,000,000 because of the rabbits. The calamitous interference with the balance of Nature involves a vicious circle, for the hope of permanent relief is increase in the agricultural population so that concerted and widespread elimination may be organised, but this increase is checked because the rabbits tend to make the settlers' work economically hopeless. Trapping and poisoning, netting and inoculation, have been tried with persistence, but the prolific multiplication of the rabbit continues to defeat man's efforts. Attention is being re-directed to the Rodier method, which has proved effective in areas of considerable size. Mr. W. Rodier suggested that doe-rabbits should be killed in as large numbers as possible, but no bucks. In the areas experimented with, the result was that the bucks killed the helpless young and also that the does were persecuted to death by the demands of the bucks. In other words, the polyandry became so intense that the females perished in large numbers. The method has experimental facts in its favour, and it is applicable to other pests such as rats and sparrows. A practical difficulty is in distinguishing the sexes before the act of killing.

WE regret to learn that on the afternoon of September 20, a violent explosion followed by fire occurred in the Dynamometer Laboratory of the Bureau of Standards, Washington, D.C. One man was killed instantly, three others injured so seriously that they died during the night, and four others seriously burned or cut. The heroism of the survivors of the staff in rescuing the injured from the furiously burning wreckage and in shutting off the electric circuits and the ammonia valves, minimised the loss of life and property. The explosion occurred in the altitude chamber which is used in testing the performance of aircraft engines under the conditions of low pressure and temperature obtaining at high altitudes. At the time of the accident the room was being used in investigating the performance of an automobile engine, at temperatures corresponding to winter operation, using various grades of gasoline. The work was intended to determine the possible increase in gasoline production per barrel of crude oil, with the accompanying conservation of oil resources, by the use of gasoline of lower volatility. The explosion was due to the ignition of an explosive mixture in the chamber. The men who were killed are: Logan L. Lauer, Urban J. Cook, Stephen N. Lee, and Joesph Kendig; while those injured are: Henry K. Cummings, Frank E. Richardson, Roger Birdsell, George W. Elliott, C. N. Smith, and R. F. Kohr. Most of these men were college graduates with experience and skill in research work, and a grave blow to science and engineering must be added to the human loss to their families and colleagues. Thus grows the long list of those who have given their lives for the increase of human knowledge and welfare.

THE first number of an important and interesting publication, *The British Journal of Experimental Biology* (Edinburgh: Oliver and Boyd. Quarterly, 12*s.* 6*d.* net; annual subscription, 40*s.* net) has recently been issued from the Animal Breeding Research Department of the University of Edinburgh, with Dr. F. A. E. Crew as editor in chief. The experimental method has become so indispensable in biological research that it is perhaps remarkable that no special journal has hitherto been devoted in Great Britain to its results, though America and Germany have long possessed such media of publication. The British journal, however, covers a wider field than any existing publication, as is sufficiently evident from the fact that the contributions to the first number are drawn from such diverse institutions as the Animal Breeding Research Department, Edinburgh, the Zoological Departments of the Universities of Edinburgh and Oxford, the Physiological Department of the University of Oxford, and the Natural History Department of the British Museum. Of late years there has been a strong tendency towards over-specialisation among working biologists and the new journal should do good service in promoting the unification of biological science. We are glad to note that it is the intention of the editors to publish regular reviews of recent progress in different fields of research; the critical summary on that very modern branch of biological science known as tissue culture, by H. M. Carleton, which appears in the present number, shows

how valuable a feature such reviews are likely to be. The journal is very attractive in appearance; both letter-press and illustrations are excellent and the price is moderate. We wish it all success, and especially a large body of subscribers.

"The Natural History of Wicken Fen," Part I. (Cambridge: Bowes and Bowes), which is to continue appearing until the volume is completed, under the general editorship of Prof. J. Stanley Gardiner and Mr. A. G. Tansley, is a very desirable record of public-spirited action by entomologists and botanists, supported by the National Trust for Places of Historic Interest or National Beauty. The Trust now holds for the benefit of the nation 521 acres, which include the greater part of the old undisturbed fenland in Wicken Sedge Fen, St. Edmund's Fen, and Burwell Fen, and has obtained leases of other areas. Mr. A. H. Evans, the secretary of the local committee formed in Cambridge in 1914 to further the purchase and preservation of the fenland, states that the Trust is able to look forward with confidence to the early purchase of a further 60 or 70 acres if funds are available. Mr. Evans reports that "very little more remains to be done in this direction," an eminently satisfactory state of affairs for which we have to thank many generous donors, but notably the late Mr. G. H. Verrall, of Newmarket, an ardent entomologist who realised the value of the undisturbed fenland to the student of insect life. The volume now commenced is to place on record the history and the biology of the fenland, and the present part contains Mr. Evans's history of the fens, with especial reference to Wicken Fen, and of their drainage and its effect upon the fauna and flora, together with an account of the butterflies and moths of Cambridgeshire by W. Farren, which is substantially the same as that appearing in the British Association Handbook for 1904. The local committee has wisely decided not to leave the fen "to Nature," which, as the secretary points out, would mean eventually the formation of a tangled impenetrable thicket of the tall coarse sedge (*Cladium Mariscus*) shaded by alien trees, but to see that excessive growth is thinned out and the waterways kept so that the winter floods may profit the ground. The characteristic fen country has never been an untouched wilderness, but so far back as its history is known the sedge crop has regularly been cut, being once of considerable value.

Sir E. Sharpey Schafer is to deliver the first Victor Horsley Memorial Lecture at the Royal Society of Medicine on Thursday, October 25, at 5 o'clock, taking as his subject "The Relations between Surgery and Physiology."

The sixth annual Streatfeild Memorial Lecture will be delivered in the Chemical Lecture Theatre of the Finsbury Technical College, Leonard Street, E.C.2, at 4 o'clock on Thursday, October 25, by Mr. E. M. Hawkins. The subject will be "Analytical Chemistry," and admission will be free.

The eighth annual meeting of the Optical Society of America will be held at Cleveland, Ohio, in the Case School of Applied Science, on October 25-27. The address of the retiring president, Dr. L. T. Troland, will be on "The Optics of the Nervous System." Prof. A. A. Michelson will read, by invitation, a paper on "The Limit of Accuracy in Optical Measurement," and Mr. F. A. Whiting, director of the Cleveland Museum of Art, will address the Society on "The Optical Problems of an Art Museum." A number of papers on general optics, vision, colorimetry, photometry, spectroscopy and instruments will also be presented.

The programmes for the meetings of the Royal Microscopical Society during the coming winter session have been issued, and the Society is to be congratulated on the excellent series of papers and communications which will be submitted for discussion. The section dealing with the industrial applications of the microscope has a specially attractive list, and in addition to the large number of exhibits, the practical demonstrations shown will be a leading feature at each meeting. Arrangements have been made for communications and discussions dealing with coal, petrology, metallurgy, textiles (cotton and linen), paper, bee-keeping, and poultry-keeping. A further attraction of the meetings of the Industrial Applications Section will be a series of lecture demonstrations, which will embody a practical course of instruction in the manipulation of the microscope. These will be given by Mr. J. E. Barnard, and a detailed syllabus of the same will be forwarded on application to the secretary to the Society, 20 Hanover Square, W.1.

The latest news of Mr. K. Rasmussen's expedition to Arctic Canada has been brought to Europe by Mr. Birket-Smith, who has returned to Copenhagen. According to the *Times*, Mr. Rasmussen had reached Pelly Bay, near the Magnetic Pole, at the end of April on his way to Alaska and Siberia in his endeavour to trace the route of Eskimo migrations. Mr. P. Freuchen is following the Eskimo track via Baffin Land, Lancaster Sound and Ellesmere Land to Thule in north-western Greenland. Mr. Birket-Smith completed his task of visiting the inland Eskimo tribes in Melville Peninsula and Rae Isthmus.

The *Times* publishes an account of the travels in Spitsbergen last August of the Merton College expedition. The original project of exploring North-East Land had, as was fully expected, to be abandoned. It is far beyond the scope of a summer visit. The vessel carrying the party was able to penetrate Hinlopen Strait from the north, land a sledging party on the western shore and reach Ulve Bay on the south coast of North-East Land. On the pack closing in, a retreat was made northward along the strait and a brief visit was paid to the north coast of North-East Land. Pack ice prevented progress beyond Cape Brunn and the vessel was forced to return. After a visit to Klaas Billen Bay, where the sledging party was picked up at Camp Bruce, the expedition returned to Norway. On the west side of North Cape was found a canvas tent bag which has been identified as a relic of the German Expedition of 1912 and doubtless belonged to Lieut. Schroeder Stranz, who lost his life in an attempt to sledge over insecure sea-ice.

Bibliography of meteorological literature, No. 4, has recently been issued by the Royal Meteorological Society, having been prepared with the collaboration of the Meteorological Office. It deals with all meteorological publications and articles on meteorology recently received, giving the titles and references where the literature is to be found. The division of the subject-matter under specified heads enables a would-be student to determine the helpful line of reading which he is desirous of prosecuting, without loss of time. Divisions are given for the several meteorological elements, such as atmospheric pressure, temperature, solar radiation, aqueous vapour and cloud, rain, wind, storms, and weather forecasting, with other allied subjects.

We have received a copy of the Report of the Proceedings of the Natural History Society of Bishop Stortford College for 1922. It is the first report published by the Society, and contains a list of the plants found in the district during the years 1920–1922, an account of the more interesting Lepidoptera occurring during 1922, and a note on the birds of the year. A list of the more important additions to the school museum during the year and a general account of the activities of the Society, especially in the maintenance of vivaria and aquaria, are added. The successful attempt to induce the viper to breed in captivity is a notable achievement. The Society can be congratulated on having got together a nucleus of enthusiastic and active workers, and we hope the publication of this report will stimulate its members to increased and more sustained work on the fauna and flora of the district.

We have received from Messrs. Watson and Sons, Bulletin 29 S. on diathermy apparatus. The introductory remarks are reprinted from an article by Dr. E. P. Cumberbatch, who has made important contributions to this subject. This foreword explains clearly the methods which are necessary for the production of sustained oscillations of the right frequency for the purposes in view, and also gives some account of the surgical and medical uses to which the diathermy currents can be put. The early designs of the instrument have been much improved so as to allow a large output of these currents, and the spark gap, which has often proved the weakest feature of the instruments, is now run in an atmosphere of coal gas; if this is not available, petrol or acetone may be used. The bulletin is illustrated by various parts of these machines and by a great variety of electrodes for the various cavities of the body.

The Cambridge University Press announces the forthcoming publication of "The Archæology of the Cambridge Region," by C. Fox, which will form a topographical study of the bronze, early iron, Roman, and Anglo-Saxon ages, with an introductory note on the neolithic age. The object of the work is to provide a basis for future detailed study, period by period, of the archæological remains of the district and of the many problems connected with them.

Our Astronomical Column.

Photographic Magnitudes of Satellites of Jupiter.—Mr. Seth B. Nicholson has made a careful study by photography of the magnitudes of the eighth and ninth satellites of Jupiter. Reduced to mean opposition they are 17·6 mag. and 18·6 mag. respectively. Assuming albedoes similar to that of Jupiter III (Ganymede), the diameters are about 30 miles and 20 miles.

Perturbations by the Method of Quadratures.—In 1908, Dr. P. H. Cowell introduced the method of following the perturbed motion of a planet or comet by calculating the forces acting in three directions mutually at right angles, and so obtaining the second differences of the x, y, z co-ordinates of the body; being given the initial values, the successive ones are then formed by addition of the differences.

Mr. B. V. Noumeroff has lately improved the method in a paper in vol. ii. of Publications de l'Observatoire Astrophysique de Russie. Mr. Commendantoff contributes a paper to *Astr. Nach.*, No. 5249, explaining the method and applying it to form positions of Ceres from 1913 to the present time. The Nautical Almanac has discontinued its ephemeris of the four bright asteroids, and since then regular ephemerides have not been available.

The point of the method is the use of new co-ordinates formed from x, y, z by multiplying them by a factor so chosen that the differences between the second and the sixth disappear, which greatly simplifies the calculation. The first approximation, using Jupiter perturbations only, at 40-day intervals, represents the place of Ceres for ten years with no error exceeding 15 seconds of time, which is sufficient for a finding ephemeris; it is further shown how the calculated co-ordinates may be improved when later observations are available. The method appears to be worthy of careful study.

Studies in Stellar Masses.—Many recent studies in this field have been mentioned in this column. Dr. E. Hertzsprung contributes another to Bulletin No. 43, Astron. Instit. of Netherlands. He classifies 14 pairs of known orbit elements and parallax; they include the interferometer results for Capella and the eclipsing variable β Aurigæ; the mass of each component is deduced and the logarithm of the mass plotted against the quantity $m+5 \log p$, where m and p are the apparent magnitude and parallax respectively. The graph connecting the two is nearly linear, showing a close correlation between mass and absolute magnitude, a result reached by other investigators. An expression using first and second powers of log mass is preferred, as it gives a better fit; it is noted that the formula fits well for the sun.

A table is given enabling the parallax to be deduced when the magnitudes and orbit elements are known. The star ζ Orionis is discussed. This star has a motion in position angle of 1° in 9 years, but the arc described is too short for finding an orbit. Jackson found the hypothetical parallax 0·016″ assuming a mass double that of the sun. The parallax found from the new formula is 0·0038″, which is regarded as more trustworthy. It agrees well with other estimates of the distance of the Orion group.

Dr. Hertzsprung appeals to parallax observers to pay special attention to stars the orbit elements of which are either known or are likely to be determinable before long.

Research Items.

FIRE-MAKING ON THE GOLD COAST.—In the September issue of *Man*, Mr. A. W. Cardinall describes the use of the flint and steel in fire-making in the northern territories of the Gold Coast. The tinder used is cotton from the kapok, and is carried about in all sorts of receptacles—cotton or leathern bags, or more rarely in the more primitive way in the hollowed-out seeds of the fan-palm. Only one case of sacred fire is recorded where the fire is maintained, more or less permanently, outside the chief's compound: there is no special rite observed in lighting it, but no one may take fire from it. The fuel used is dried cow-dung, and in the rains the fire is allowed to go out. Sacrifices are made to it, some of the blood and bones of the victims being placed in a pot laid on the top of the fire. Only the chief and one other man, not identified, are allowed to eat the flesh of the sacrifice.

THE OCCURRENCE OF THE LIZARD IN MAORI CARVINGS.—In the *New Zealand Journal of Science and Technology*, March, 1923, Mr. Elsdon Best of the Dominion Museum notes that one of the remarkable features of Maori carved work is its lack of natural forms, particularly of the local flora. Some animals are delineated, but none so faithfully resembling the original as the lizard. The type known as Manaia seems to have been confused with the lizard, possibly because this is one meaning of the word, but the Manaia form is really the old Indian motif of Vishnu flanked by two Garudas, the powers of Good and Evil. Mr. Best thinks it probable that the introduction of the lizard or crocodile into carved designs originated in the western Pacific, possibly in Indonesia. He gives numerous examples of superstitions connected with lizards, one being that the Maori is said to believe that the spirits of his ancestors revisit the earth in the form of lizards. This may to some extent account for its introduction into Maori art.

HAWAIIAN LEGENDS.—A collection of Hawaiian legends by William Hyde Rice forms Bulletin No. 3 of the Bernice Pauahi Bishop Museum at Honolulu. The narrator is the son of missionaries who arrived in Hawaii in 1840, and he has been familiar with the Hawaiian language since his earliest childhood. He has been a member of the House of Representatives, and a Senator, and was Governor of Kauai under Queen Liliuokalani until after the revolution of 1898. The legends are fairy tales pure and simple with no underlying mythological meaning. They were told by the bards or story-tellers, either itinerant or attached to the courts of the chiefs, where alone the stories were to be heard. Some had historical foundations now forgotten, others were efforts of the imagination. Some of these legends Mr. Rice remembers having heard as a boy, and places mentioned in the stories were pointed out to him. Among the legends are those of Pele the fire-goddess, the Rainbow Princess, and Ulukaa the rolling island. Another tells of the Menehune, mythical dwarfs only two or three feet high, who were tremendously strong but ugly of face. They were credited with all sorts of magical powers and perfect skill, but would only work one night on any construction. If not completed it was left undone. Other stories are those of Kawelo the hero of Kauai, of Paakaa and his son Ku-a-paakaa, of Kana the strong, of the beautiful Kaili-lau-o-kekoa and of Makuakaumana, the man who was swallowed by a big fish, and several others. A glossary of Hawaiian terms with notes is given as an appendix, and a portrait of Mr. Rice forms a frontispiece. The work is a valuable addition to the lighter legendary lore of Hawaii.

CERAMICS AND MINERALOGY IN JAPAN.—Examples of the thoroughness with which Japanese scholars bring the most modern developments of research to bear upon economic problems, and at the same time welcome economic problems as enlarging scientific knowledge, are to be found in Vol. 1, No. 3 of the third series of Science Reports of the Tôhoku Imperial University. The outcome in this case is that mineralogists will learn much from experiments undertaken for the ceramic industry, since the scientific results that are obtained in the course of the investigations are recorded as matters of fundamental interest. Shinjo Satoh, for example, in his work on fire-clays, observes (p. 200) that kaolinite loses its combined water between 400° and 600° C.; that an internal change takes place between 900° and 1000° C.; and that between 1200° and 1300° C. a further internal change occurs from the recombination of free silica and aluminium silicate that became dissociated at a lower temperature. The gradual corrosion and ultimate fusion of quartz grains in a magma formed from lead glass and clay pulverised together is, among many other instructive matters, illustrated by microscopic sections (p. 195 and Pl. 11). Kunikatso Seto (p. 219) gives a number of new analyses of felspars, mostly from classical localities, and S. Kōzu and M. Suzuki (p. 233), following Des Cloizeaux, have studied the influence of temperature on the optic axial angle of sanidine. The locality and chemical composition of the specimens are, we think, not stated. The considerable increase in the optic axial angle recorded for high temperatures by Des Cloizeaux is found to be due to an abrupt change at about 900° C. X-rays have been utilised, and the Laue diagrams obtained show that this change is not accompanied by alteration of the space-lattice.

PHYSIOLOGICAL CLASSIFICATION OF OATS.—Investigations relative to the yielding and other properties of oat varieties under different conditions of soil and climate are described by M. G. Jones in Bull. C. No. 3, of the Welsh Plant Breeding Station. Trials were carried out with autumn and spring sown varieties from 1920–2, aspects of their economic and agricultural behaviour being considered. The different varieties are compared with one another in detail, with special regard to such points as the relation between the yield of straw and various other factors, for example, the time taken to reach maturity, the date of emergence of the panicle, average height of the plants and the yield of grain. The tillering capacity of the same varieties in different years was also considered. The information gained from the experiments indicates the possibility eventually of classifying varieties of oats on a physiological basis in such a way as to afford practical guidance to the farmer in the selection of his seed corn.

EFFECTS OF RADIUM RADIATIONS ON TISSUES.—The July issue of the quarterly journal *Radium* contains a number of papers dealing with the effects of the radiations from radium upon the tissues. These papers have for the most part been published in American Medical Journals and indicate the extent to which radium is used in many conditions other than malignant disease. A paper by Bailey and Bagg deals with the effects of irradiation on foetal development in the lower animals. On the basis of this work, they consider that if radiation is applied in late pregnancy, though it may not produce gross abnormalities at birth, it may hinder the growth and development of the child in later life. MacNeal and Willis describe a case of squamous-cell carcinoma

forming on the hand of a radiologist after too frequent exposures to tubes of radium which he handled during the course of clinical work. A new device for the application of radium to the tonsils is described by Stewart, a previous article in this issue upon the treatment of neoplasms of the tonsil by Quick showing that good results are obtained by methods which ensure a thorough irradiation of the affected parts.

CRETACEOUS OVERFOLDING IN THE ALPINE REGION.—A detailed review of the results of recent observations on the Alpine overfolds, and particularly of L. Kober's work on the deeply penetrating "Tauernfenster" in 1921, is given by A. Tornquist of Graz in the *Geologische Rundschau*, vol. 14, pp. 110-145 (1923). The title, "Intrakretazische und alttertiäre Tektonik der östlichen Zentralalpen," shows how the movements that have produced successive overfolded sheets have been traced back into the Cretaceous period, the most striking evidence being the unconformable deposition of the Gosau beds upon the earliest overfolded series. The notice of Kober's "Bau und Entstehung der Alpen" in NATURE, vol. 112, p. 322, gave some hint of these conclusions.

METEOROLOGY IN THE EAST INDIAN SEAS.—The Meteorological Chart of the East Indian Seas for September, recently issued by the Meteorological Office, is of considerable interest. Winds and ocean currents are dealt with in detail, together with the normal atmospheric pressure and temperature of air and sea, as well as other matter of importance to the navigator. The chart comprises the Red Sea and covers the area from the Cape of Good Hope to the China Sea and Western Australia. It is well shown how under normal conditions the ocean current responds to the prevailing wind. The winds are under the direct influence of the several areas of high and low barometer, and in any position on the chart the seaman can interpret the changes he is experiencing, in normal circumstances, and can estimate how soon he may expect a change of conditions. The observations used extend over a period of about sixty years. On the back of the chart ocean currents are discussed for the track between Honolulu and Fiji. Current-roses are used on a system analogous to the wind-roses on the face of the chart, a system somewhat open to question, and for any extended alteration in this direction expert knowledge is desirable, if possible equal to that given to the general system, hitherto used, of showing ocean currents. A comparison is given of temperature in fixed and in portable screens on board ship. Probably the position of the screen must be left chiefly to the commander of a ship, with cautious suggestions. The usual form of screen used at sea, supposing the single louvre screen to be still in use, has to be screened itself, as single louvres are not effective.

RADIOACTIVITY AND SOLAR RADIATIONS.—It has been asserted that radioactivity is independent of all known physical agents; but M. A. Nodon, in the *Comptes rendus* of the Paris Academy of Sciences of June 11, describes additional experiments, which seem to confirm his previously expressed view that the process is greatly accelerated by very penetrating radiations from the sun. These radiations are able to penetrate a thin sheet of lead, the absorption being greater the higher the atomic number of the screen employed. The action is more marked during periods of solar activity.

TEMPERATURE OF THE CROOKES DARK SPACE IN GLOW DISCHARGE.—Observations on the glow discharge have recently been made in the Physikalisch-Technischen Reichsanstalt at Charlottenburg by Herr A. Günther-Schulze. He measured the energy delivered to the cathode, and there converted into heat; and found the ratio that it bore to the total energy delivered to the cathode and the dark space; this amounted to 72 per cent. in argon at 1·83 mm. pressure, 39 per cent. in hydrogen at 2·37 mm., and as much as 73·4 per cent. in nitrogen at 3·53 mm. If the free path of the atoms corresponds to room temperature, or the dark space is cool, this ratio is about 20 per cent. The natural conclusion is that the dark space is heated by the collisions taking place in it between the positive ions and the gas molecules; and a calculation of the probable temperature, in the case of one of the experiments with nitrogen, leads to the figure 720° C. The electrical energy expended in the dark space appears to be sufficient to account for this rise of temperature. The length of free path at this temperature is such that a considerable proportion of the ions pass through the dark space without colliding with a molecule, and the number of average free paths between the boundary of the dark space and the cathode must be small. All this agrees with the fact that, when the velocity of canal-rays is measured, a marked proportion have the velocity corresponding to the total cathode fall. The free path of the electrons is four times as great as that of the positive ions, so that most of them cross the dark space without collision, and begin to produce ions when they reach the negative glow, the maximum number per electron being equal to cathode fall divided by ionisation voltage. It follows that the ratio of the electronic current to the ionic current in the dark space is about 1 : 10.

FREE PATH OF SLOW ELECTRONS IN MONATOMIC GASES.—Using an incandescent cathode, a cylindrical grid surrounding it, and a concentric cylindrical anode at a voltage very slightly higher than the grid, it is found that the form of the characteristic curve showing the relation between anode current and grid voltage is strongly influenced, in the case of argon, by the abnormally long free path of very slow electrons through this gas. Minkowski and Sponer in a paper dated March 27, published in the *Zeitschrift für Physik*, give the curves obtained with argon, krypton, xenon, neon, and helium. For the first three gases there is a sudden rise in the current curve at zero voltage, followed by a sudden drop; with neon and helium, there is a less marked sudden rise, followed by a more gradual rise; in all these cases, however, and also in the case of mercury vapour, the shape of the curve near zero volts is to be explained by the fact that the free path of slow electrons is abnormally long. In the case of the inert gases, certain sharp upward bends in the succeeding portions of the curves are interpreted as being due to the fact that the electrons have reached the velocity required either to excite the atoms or to ionise them; and, making the proper corrections, the voltages agree quite well with those which direct measurement shows are needed to produce these effects. When the electrons strike the atoms in inelastic collision their velocities are reduced, their free paths are increased, and, as a result, the current becomes greater. With argon, a number of these sudden jumps of current are observed, corresponding to two different excitation voltages, to the ionisation voltage and to twice one of the exciting voltages or the sum of the two; this implies that the velocity of the electrons, at one of the last-mentioned points, is such that it can collide with an atom exciting it, and retain sufficient energy to excite another atom.

Report of the British Broadcasting Committee.

THE Committee appointed by the Postmaster-General on April 24 last to consider the present position of broadcasting in Great Britain and make recommendations for the future, made its report to him on August 23; the document (Cmd. 1951, H.M. Stationery Office, price 9*d*. net) was issued to the public on October 1.

By the terms of reference, the Committee had to consider: (*a*) Broadcasting in all its aspects; (*b*) the contracts and licences which have been or may be granted; (*c*) the action which should be taken upon the determination of the existing licence of the Broadcasting Company; (*d*) uses to which broadcasting may be put; and (*e*) the restrictions which may need to be placed upon its user or development.

The Report, which is admirably drawn up, has been signed by all the members of the Committee; reservations are, however, made on a few points by three of them. There is every evidence that very careful consideration has been given by the Committee to the many matters associated with the present-day broadcasting problem; and certain important recommendations are made in its Report. The task of the Committee has been one of peculiar difficulty, owing to the existence of a licence from the Post Office to the British Broadcasting Company for the operation of a scheme which, while still having some eighteen months to run, has in certain respects broken down in practice. The Committee has wisely decided to disregard to a great extent this complication and has dealt with the situation practically as though the Government had a free hand.

In view of the possibility that all large communities may eventually demand this inexpensive service, and that Imperial and international broadcasting services may eventually be established, the Committee considers that "the control of such a potential power over public opinion and the life of the nation ought to remain with the State, and that the operation of so important a national service ought not to be allowed to become an unrestricted commercial monopoly." It is further pointed out that a technical reason for such control also exists: all wireless telegraphy and telephony has to be conducted within a limited group of "wave-lengths," and every new wireless station takes up a certain "waveband," which no other sending station within a certain radius should be permitted to use. These "wavebands" must, the Committee considers, be regarded as a valuable form of public property, and the right to use them for any particular purpose should be authorised only after careful consideration and in such a way that the public interest may at all times be fully safeguarded.

The Committee recognises that broadcasting is still in its infancy and that new applications of it are likely to arise from time to time in many directions. It is of opinion that, if conducted on proper and sound lines, broadcasting will be of great educative value, both directly and indirectly, and it has been much impressed with the widespread enthusiasm which broadcasting has aroused. The great interest in wireless telegraphy and telephony promoted by broadcasting in almost every class of society cannot but tend, the Committee foresees, to produce beneficial results, stimulating as it does experiment and research. "The listener," the Report says, "may perhaps become an experimenter; the experimenter may possibly become an inventor."

The Report deals briefly with the events which led to the appointment of the Committee and gives an outline of the present scheme, its merits and defects being set out. The Committee places on record the fact that the evidence placed before it "demonstrates that the British Broadcasting Company have shown enterprise and ability of a high order in carrying out their undertaking and have done much valuable pioneer work in the face of many difficulties." The Report also comments upon the objections which have been raised by certain manufacturers and dealers to the present scheme. The Committee expresses the following opinions thereon. It agrees with the view that it is wrong in principle to attempt to control the manufacture and importation of wireless apparatus by means of licences issued by the Postmaster-General. As regards the remaining objections, it agrees that the scheme gives the British Broadcasting Company unusual powers; the Committee, however, has had no proof that the Company has made any improper use of its position. The scheme for levying a contribution on apparatus from the manufacturers was, the Committee points out, imposed by the Government as a condition of the broadcasting licence which the manufacturers desired.

The first of the recommendations contained in the Report relates to a matter affecting the Controlling Authority. The Committee considers that the questions involved in broadcasting are so complex, and the decisions to be taken so various and require so much technical and other consideration, that a Standing Committee (unpaid) should be set up by Statute to assist the Postmaster-General in the administration—technical, operative and general—of broadcasting. It is recommended that this Committee, for which the name "Broadcasting Board" is suggested, should be composed of an independent chairman, preferably a specially qualified member of the House of Commons, nominated by the Postmaster-General, and twelve members—of these two should be specially qualified persons nominated by the Postmaster-General, and the remainder should be drawn from certain interests or bodies named in the Report. In connexion with this recommendation, the Committee thinks that broadcasting may eventually become "so great a national responsibility as to demand the creation of a small paid body of experts, to whom (always subject to the Postmaster-General) its control should be entrusted."

Sir Henry Norman, a member of the Committee, makes an important reservation in relation to the composition of the proposed Board. In his opinion "a heterogeneous Board of thirteen members, giving voluntary service, eleven of them not necessarily with special knowledge of the subject and possibly without technical knowledge at all, presided over by a member of the House of Commons, who would, of course, be chosen from the political party in power, and whose tenure of office would be subject to political exigencies, would be inefficient, would carry little authority, and its proceedings would therefore be for the most part futile." Sir Henry is in favour of the appointment of a highly-qualified and well-paid Broadcast Control Board, say, of three members; that is to say, he would prefer that immediate effect should be given to that part of the Committee's Report which recommends the creation at a future date of a small paid body of experts for the control of broadcasting.

The arguments for and against the operation of the broadcasting services by the State are set out in the Report. The Committee considers that the objections to State operation of the service outweigh the advantages; at the same time, it is of opinion that no licence issued by the Postmaster-General

should preclude the Government from using its own wireless stations for the broadcasting of such information as may be deemed desirable, subject, of course, to the ordinary broadcast programmes being interfered with as little as possible. Mr. C. Trevelyan, a member of the Committee, expresses regret that his colleagues were unable to agree to the operation of broadcasting by the Post Office. He is of opinion that a situation may easily arise in which this may be the only satisfactory possibility and gives reasons for the views he holds.

In dealing with the means of securing widespread reception with the cheaper types of receiving sets, the Committee points out that most of the existing difficulties might be avoided or reduced by the provision of a considerable number of transmitting stations of lower power than those already existing. The possibility of employing relay stations and linking them up by Post Office telephone trunk lines to main centres is also touched upon. Developments in these directions depend upon certain technical factors, and the outlay for thus dealing with the whole country would be large, both as regards the wireless stations and the land lines. Such a scheme, the Committee points out, would enable great numbers of persons to use "crystal" receivers, and it is likely the revenue from licences would be correspondingly increased. So far as future developments are concerned, the Committee thinks that the greatest latitude should be left to the Controlling Authority, and is a matter in which it would be unwise for the Committee itself to attempt to define the policy which should be adopted. A recommendation is, however, made that the licence issued to the British Broadcasting Company, which has the requisite organisation and technical and other experience, should, subject to certain variations in its terms indicated in a later part of the Report, be continued.

The alternative methods of meeting the cost of broadcasting and the several considerations that come into play are comprehensively dealt with in the Report. Having considered the evidence placed before it on the subject, the Committee has come to the conclusion that, in order to cover the cost of running its eight stations and to pay a dividend on its capital at the rate of 7½ per cent. per annum, the British Broadcasting Company requires a revenue of 160,000*l.* a year—or, if allowance is to be made for future developments and improvements, not less than 250,000*l.* a year. Of the methods of raising revenue proposed, the Committee entirely rejects the one containing a proposal that the cost of broadcasting should be met wholly or partially out of public funds. With regard to the suggestion made to it that a substantial contribution towards the cost of the service should be obtained by means of a system of licensing the manufacture and sale of wireless apparatus, the Committee says that the proposal merits careful consideration, but it is unable to recommend its adoption.

In dealing with the existing method of raising revenue by means of fees collected on licences issued to owners of receiving apparatus, the Committee has had to consider the objection which has been raised in principle to a Government Department handing over public revenue collected by it to a private individual.

The Committee is of opinion that the arguments advanced against the adoption of this method of providing funds for broadcasting are based on an incorrect conception of the nature of the transaction and recommends the continuance of the present arrangement whereby revenue is collected by means of licences for receiving sets, a part of which is handed over to the British Broadcasting Company. The aim of the Post Office should, the Committee thinks, be to obtain sufficient revenue from licence fees (*a*) to cover administrative expenses in connexion therewith with a safe margin, and (*b*) to provide the necessary contribution to the cost of the broadcast programme. In the event of a considerable increase in the number of licences, the resulting surplus should, it is suggested, be devoted (i.) to reducing the licence fee; or (ii.) to improve the service; or (iii.) to both these purposes. As the Post Office authorities estimate that the cost in connexion with the issue of licences is unlikely to exceed 2*s.* 6*d.* per year per licence, an amount of 7*s.* 6*d.* per licence would be available, if required, to meet the cost of all broadcasting services. The total number of licences issued up to the present is about 170,000, and there are about 30,000 applications for experimental licences held in suspense, making a total of about 200,000. It is impossible, of course, to say what is the number of unlicensed stations; it is stated in the Report that the number is probably nearer 200,000 than 100,000. The Committee is of opinion that, if a high standard of programmes is maintained, it is not unlikely that within a few years the number of broadcast listeners may rise to a million or more. In view of the possibility of a very considerable increase in the number of licences, the Committee suggests that under any new arrangement a sliding scale should be adopted in relation to the proportion of the licence fees to be paid to the operating company or companies.

The Committee recommends that the marking of apparatus should be abandoned and one uniform licence introduced for broadcast reception and another for experimental work. It is further recommended that the broadcast licence should be placed on sale at Post Offices and issued on payment of the fee without any formalities or questions. It is pointed out that the Post Office would thereby be relieved of the difficult and somewhat invidious duty of determining whether applicants are genuine experimenters or not. With a view, however, of safeguarding neighbouring installations from interference, it is recommended that a clause should be inserted in the new licence in the following terms:—"The station shall not be used in such a manner as to cause interference with the working of other stations. In particular, back-coupling must not be used to such an extent as to energise any neighbouring aerial." Disregard of this condition should, it is suggested, render a licence liable to summary cancellation, and, further, that provision should be made for levying a penalty in cases where a licensee can be proved to have repeatedly caused serious interference. It is also suggested that for purposes of meeting cases where persons set up and use unlicensed receiving stations, statutory powers should be obtained similar to those already possessed by the Customs and Excise Department in connexion with the licences they control, so as to place the Postmaster-General in a position (*a*) to call upon suspected persons to fill in a form of declaration showing whether they are liable to a licence fee or not; and (*b*) to accept a compromise fine in the case of a minor default as an alternative to prosecution.

Having regard to the existing agreement between the Post Office and the British Broadcasting Company, the Committee recognises that it would not be possible for the Postmaster-General to introduce any change in the present scheme whereby the rights of the Company would be adversely affected, except as a matter of negotiation between the parties thereto. It is of opinion that the immediate adoption of its

recommendations as a whole would entail certain adverse effects on the British Broadcasting Company and its constituent members. In consequence, the Committee suggests that if its recommendations are carried out forthwith, the proportion of the licence fee to be paid to the Company should be increased from 5*s.* to 7*s.* 6*d.* per licence, subject to the application of the sliding scale already referred to; this 7*s.* 6*d.* rate to take effect from November 1, 1922, when broadcast receiving licences were introduced. It is further recommended that the period of the Company's revised licence should be extended for two years beyond the original term, *i.e.* to January 1, 1927. It is proposed that in return for these concessions the Company, on its part, shall agree (*a*) to the immediate application of the scheme recommended; (*b*) to the revision of its articles of association, in order to provide (1) for dealers and retailers of wireless apparatus to obtain at least one 1*l.* share in the Company, (2) for members of the public to take up shares, if and when fresh issue of capital is made, and (3) for securing adequate representation on the Board by the new membership; and (*c*) to the abolition of the deposit of 50*l.* now required from members.

Mr. J. C. W. Reith (the General Manager of the British Broadcasting Company), a member of the Committee, makes a reservation as to the conditions proposed in relation to the issue of uniform licences and as to the general application of the scheme recommended; he is of opinion that under the proposed scheme the interests of the British manufacturers will not be sufficiently safeguarded.

On the technical side, the Committee makes certain important recommendations as to wave-lengths and the hours during which broadcasting services may be provided. It considers that arrangements should be made for the greatest possible extension of the existing broadcast band of wave-lengths (350 to 425 metres), preferably by the allocation of a band from 300 to 500 metres, excluding 440 to 460 metres, and that all possible steps should be taken to protect the band allocated to broadcasting from interference by other services. The Committee further suggests that the present restrictions on the hours of broadcasting should be removed, so that additional broadcasting facilities might be provided. These changes, it is considered, can be readily introduced without detriment to the other interests which have to be considered.

In relation to the broadcasting programmes, the Committee states that the British Broadcasting Company has achieved a large measure of success in gauging the public taste and providing programmes, and suggests that there should be a gradual extension of broadcasting of news, under proper safeguards; it is also urged that more latitude should be given to the broadcasting of special events without regard to hours. Finally, the Committee places on record its conviction that the Postmaster-General should remain the final arbiter when any question is raised as to what kind of matter may or may not be broadcasted.

Contemporaneously with the issue to the public of the Report of the Broadcasting Committee, a statement was sent to the Press by the Post Office; therein it is announced that the Postmaster-General feels that it is not possible for the scheme recommended by the Committee to be brought fully into operation immediately, but, with the view of the continuance of the broadcasting services, he has agreed with the Company to the introduction of a constructor's licence at a fee of 15*s.* for a limited period—the licensee must in such cases give an undertaking that, in constructing his apparatus, he will not knowingly use parts manufactured elsewhere than in Great Britain or Northern Ireland. Further, with the view of meeting the case of the 200,000 persons who are supposed to be in possession of unlicensed receiving apparatus, it is proposed to issue a special interim licence at a fee of 15*s.* also, covering present apparatus, whether home-made or purchased and irrespective of its place of manufacture, provided that this licence is taken out before October 15. In such cases no charge will be made for past usage, nor will proceedings be instituted for the failure to comply with the law. The issue of the constructor's and the interim licences will be continued until December 31, 1924, and, subject to sanction by the House of Commons, the Postmaster-General agrees to pay 12*s.* 6*d.* and 7*s.* 6*d.* out of the 15*s.* and 10*s.* broadcasting licences respectively to the British Broadcasting Company. The decision of the Postmaster-General to raise the licence fee to the home-constructor has come as a real disappointment to a very large number of them: to many of this class of listener the increase of the fee from 10*s.* to 15*s.* makes all the difference whether they can possess a licensed station of their own or do without one altogether.

An agreement has also been come to between the Post Office and the British Broadcasting Company for the modification of the articles of association of the Company on the lines recommended by the Committee. The licence now held by the Company will be prolonged, on suitable conditions, to the end of 1926; provided that the Company gives a satisfactory service and is willing to erect additional stations, should the Postmaster-General require this to be done, it is given what is virtually a monopoly during the unexpired period of the original agreement. However, the rights of the Postmaster-General are reserved, in certain circumstances, from and after December 31, 1924; thereafter not only may he, in appropriate cases, license other organisations, but he may also give them an adequate share of the revenue arising from new licences. The Postmaster-General may further (without regard to geographical area) license other services without withdrawing any part of the licence fees to which the Company may be entitled.

It is announced also that the Postmaster-General proposes at an early date to appoint an Advisory Board, as recommended by the Committee, to assist him in all important questions relating to broadcasting. Presumably this Board will be a statutory body: whatever may be the sources from which its membership is drawn, it is to be hoped that every care will be taken to avoid the creation of the inefficient type of Board so strongly condemned, and justly so, by Sir Henry Norman in the special paragraph contributed to the Report by him.

The action taken by the Postmaster-General on the Report of the Broadcasting Committee brings to a close the deadlock which has now for some months existed between the Post Office and the British Broadcasting Company. It is somewhat unfortunate that the restoration of peace between the parties to the original agreement has been purchased at the expense of a class, the home-constructors, who are deserving of greater consideration than they are about to receive. It is not at all improbable that the course of events may cause both the Postmaster-General and the British Broadcasting Company to regret that the recommendations of the Broadcasting Committee in relation to the introduction of one uniform broadcast licence have not been at once put into force.

Pioneers of Metallurgy.[1]

The relationship of scientifically trained experts to the actual work of the world is much closer than at first sight would appear. The introduction of bronze and iron into the daily life of our ancestors marked the initiation of epochs of an importance to civilisation only secondary to the advent of fire. Metals were prepared from their ores, and worked into beautiful and useful forms, thousands of years before science, as now understood, existed. So far as we know, the necessary knowledge and skill must have been arrived at by a process of trial and error; or, in other words, by the method of experiment and observation. There have been, from time to time, revivals during which the arts and crafts made great steps forward. These steps must necessarily have resulted from the revival in individual workers of the dormant interest and belief in experiment and observation, no doubt stimulated by the generally increased activity of thought in the times in which they lived. The material progress of the past has invariably been due to observation of the actual phenomena leading to experiment on, and observation of, the effect of changed conditions on these phenomena; observation followed by thought, leading to experiment, followed in turn by further thought.

While the vast majority of our fellow-men have had neither the desire nor the capacity for experiment and observation, it is impossible to avoid the conclusion that there have been from the start of the human race individuals of this type to whom civilisation on its material side has owed practically everything. Of the equally important element of thought which must follow observations if these are to lead to practical achievements much might be said. While thought must be critical in the broadest sense, it must also be constructive. In the true pioneer it must, if need be, override the purely negative function of criticism, for without courage and enthusiasm in facing the unknown no real pioneering work can be done. This type of constructive thought in its higher development is one of the rarest of intellectual qualities.

The pioneers among the early workers in metals must, like their more modern successors, have possessed some strains of this great quality, this instinct which makes for progress. Here also we find that there has been absolute continuity in the evolution of workers in metals from our prehistoric ancestors down to the designers of this laboratory, which in itself is a visible expression of the latest thought and practice in the production and manipulation of metals. One of the laboratories here is named after Henry Cort, in memory of his epoch-making work on the manufacture of malleable iron in Great Britain one hundred and forty years ago. This may be gladly accepted as an admirable illustration of the point that the qualities which make for progress are deep down in the very nature of the individual pioneer, who, in many cases, owes little or nothing to the systematic knowledge of science. In Cort's case he knew the primary object of the free exposure of molten cast-iron rich in carbon to a moderately oxidising atmosphere in which the carbon was burned away, but it is improbable that he had any theoretical idea as to how the fibrous texture of the resulting iron was produced. By trial and error he definitely ascertained the conditions of atmosphere, of temperature, and of working at each stage which would attain the desired result, and this knowledge he was able to translate into a workable process on a large manufacturing scale.

While an exact knowledge of scientific laws and methods is a tool which must be placed in the hands of the future workers in, and directors of, the metal industries, the material on which this tool is to be employed must be their own close and personal observation of facts and phenomena, and time must be unsparingly devoted to the acquirement of this habit until it becomes instinctive and automatic. Let us not forget that, in spite of our wide knowledge of scientific laws and phenomena, the skilled craftsman may still be our model in this type of observation.

[1] Abstract of an address delivered by Sir George Beilby on September 11 at the opening of the new Metallurgical Department of the University of Manchester.

American Genetical and Botanical Research.

The great amount of valuable research being accomplished in biology, genetics, and botany by the investigators of the Carnegie Institution of Washington is shown by the reports from the Departments of Genetics and Botany in the Year-Book for 1922 of the Institution. Reports are included not only of the experimental work at the Station for Experimental Evolution near New York, the Desert Botanical Laboratory at Tucson, Arizona, and the Coastal Laboratory at Carmel, California, but also from men holding chairs in various American universities, and from travel experiments in regions so far afield as South Africa and Australia. Only a few of the many lines of research of which this Year-Book contains reports of progress can even be mentioned in a short review.

We may mention Prof. W. E. Castle's continued studies on inheritance in mice, rats, and rabbits, in which the linkage relations between groups of characters are being worked out on a basis similar to the Drosophila experiments; and the further investigations of Prof. T. H. Morgan and his collaborators on the constitution of the germ-plasm in that little fly. Prof. C. A. Kofoid reports the discovery of amœbæ in connexion with such diseases as arthritis deformans (in bone marrow) and Hodgkin's disease (in lymph glands), and has also investigated various intestinal parasites. Mr. Albert Mann continues a monographic study of North American diatoms.

The work under the direction of Dr. C. B. Davenport includes many diverse fields of activity in genetics, eugenics, and animal behaviour. Co-operative breeding with mice and dogs; the study by Dr. Banta of intersexes and eyeless variations in parthenogenetic Cladocera; the continued experiments of Dr. Riddle on the metabolism of sex and other problems in pigeons; the investigations of Messrs. Blakeslee, Belling, and others on variations and chromosome relations in Datura, some of which parallel conditions discovered in Œnothera a decade ago; pedigrees of aristogenic and cacogenic families—these are but a few of the activities of this laboratory.

In botany, the report of Dr. D. T. MacDougal from the Desert and Coastal Laboratories is mainly concerned with physiological and ecological problems. The continued investigations of Dr. H. A. Spoehr and others on photosynthesis and other processes in the leaf have established a quantitative relation between photosynthesis and respiration. Dr. MacDougal continues the study of various problems of hydration and permeability in the plant cell, including the use

of a type of artificial cell. The dendrograph is also applied further in the study of the growth of trees and minute changes in the volume of the trunk.

The ecological work includes a study by Dr. Forrest Shreve of the factors influencing the altitudinal distribution of vegetation in Arizona, various observations by Dr. W. S. Cooper on the strand vegetation of the Californian coast, and on the endemic conifers of the Monterey peninsula. Dr. W. A. Cannon reports an atmometer experiment to test the evaporating power of the air in the Karroo and other parts of South Africa, and a study of the transpiring power of various Karroo plants, including species of Aloe, Gasteria, Cotyledon, and Protea. A similar series of observations on Welwitschia near Swakopmund shows that its transpiring power is very low. Full reports of many of these lines of research are either in preparation or will be published later. R. R. G.

The Mechanics of a Cyclone.[1]

A NOTEWORTHY attack is made by Dr. V. H. Ryd, in the paper referred to below, on the problem of the circulation of the air in a cyclone, the source of the energy necessary for its maintenance, and the disposal of the rising air. The cyclone considered is necessarily "ideal," with circular isobars, the pressure at any distance from the centre being determined by an arbitrary formula which gives good results for the body of the cyclone but causes a discontinuity at the boundary.

The first part of the paper, entitled "Preliminaries," leads to a series of fundamental differential equations which cannot be integrated, and in the second part a graphical method of solution is developed, by which the air-paths appropriate to the pressure distribution are constructed. This method is next applied to the more important case in which a uniform pressure gradient is superposed on the original circular isobars. The results are shown both as actual paths of air particles and as a synchronous representation of actual wind such as we see in a daily weather chart. In both cases the presentation appears to be in good agreement with Nature. From the air-paths so constructed it is easy to compute the variation of the surface area occupied by any given mass of air, and consequently the regions of rising and falling air. This is done for the surface, in Fig. 33, which is reproduced here (Fig. 1). The figures represent the percentage value by which the area changes in an hour, the broken lines referring to contractions (*i.e.* rising air), and the full lines to dilatations. The region of falling air in the north-west quadrant is of great interest and receives an important verification, with which the author was apparently not acquainted, in a chart showing the distribution of weather with reference to the centre of a depression which crossed England in November 1915 (A. E. M. Geddes in Q.J.R. Meteor. Soc., 43, 1917, p. 15).

The third part of the paper applies the results so obtained to the construction of a picture of the mechanism of travelling cyclones, supported by an actual numerical example. The ordinary temperature distribution results at great heights in a system of open, nearly parallel isobars corresponding with winds of great velocity at the cirrus level; this is termed the stationary system, and from the nature of its origin it extends with decreasing intensity nearly to ground level. Hence a travelling cyclone can be divided into four parts, namely, the ground stratum; the lower stratum of the free atmosphere in which the velocity of the wind arising from the stationary system is less than the speed of the cyclone; the central part of the cyclone, in which these two are equal; and the higher stratum, in which the velocity of the wind from the stationary system is the greater. The resulting pressure distributions, wind velocities, and vertical motions in these layers are studied, and combined in a description of the circulation of the air.

The conclusion is that the air which is thrust up in the portion of the cyclone with negative coefficients cannot escape until it reaches the highest stratum referred to above; in this stratum it is carried forward out of the system. The same conclusion applies to the descending air, which is sucked from the higher stratum to the ground level. Hence the "stationary system" provides the energy of the cyclone, and the author considers that in most cases

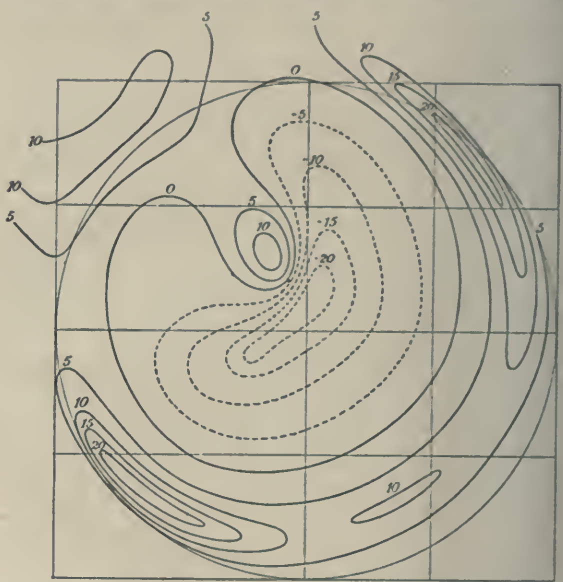

FIG. 1.—Variations of areas in a travelling depression.

the decay of an Atlantic cyclone is due to the dying out or disturbance of the stationary pressure field—a conclusion which requires further elucidation. In the last chapter attention is briefly directed to the agreement of these theoretical results with actual observations of the direction and speed of cyclones and the vertical and horizontal distribution of temperature, including the existence of a "cold front," which is thus shown to be a consequence, and not a cause, of the formation of a cyclone.

The paper is highly mathematical in treatment; this is, of course, necessary in a scientific account of new work, but it is unfortunate as being likely to deter the reader without a high mathematical equipment, although actually much of it can be read without mathematics. In view of the great interest at present taken in the "polar front" theory of cyclones and the importance of this vindication of the older view, it is to be hoped that the author will shortly present us with a more popular account, including more illustrations from Nature. It would have been better to have avoided attaching two different meanings to the symbol R, even though no confusion is caused thereby.

University and Educational Intelligence.

ABERDEEN.—The following assistants have been appointed: Anatomy, Mr. A. Lyall; forestry, Mr. E. V. Laing; mathematics, Mr. J. T. Lawrence; natural philosophy, Mr. H. D. Griffith; pathology, Mr. J. F. Davidson; physiology, Mr. J. Fiddes; surgery, Mr. W. Anderson.

CAMBRIDGE.—Of the additional annual grant of 30,000*l.* from the University Grants Committee, announced by the Vice-Chancellor in his annual address to the University, a sum of 4000*l.* annually from the total is ear-marked for the next ten years for the Women's Colleges.

ST. ANDREWS.—The induction of Prof. John Read to the chair of chemistry in the United College, and of Prof. Adam Patrick to the chair of medicine in the University, took place in the Hall of the University Library, St. Andrews, on Friday, October 5, at 4 P.M.

SPEAKING at a prize-distribution ceremony at the Maharajah of Kasimbazar's Polytechnic Institute, the new Vice-Chancellor of the University of Calcutta blessed Capt. Petavel's scheme (described in NATURE of August 26, 1922, p. 298) for establishing in Bengal co-operative educational colonies in which pupils would spend a considerable part of their time in remunerative employment on farms and in workshops. "Boys following the school and college courses as they are now, resemble," he remarked, "a flock of sheep rushing over a precipice,"—referring to the notorious overcrowding of the occupations for which alone those courses afford a suitable preparation. The scheme, however, notwithstanding its endorsement by the former Vice-Chancellor and many other Calcutta notables, still hangs fire, for want, apparently, of the funds necessary for making a start.

THE foundation stone of the first of the permanent buildings of the University of Western Australia was laid on September 1 by the Premier of the State, Sir James Mitchell. This building, which is being erected for the natural science lecture rooms and laboratories, is placed on rising ground overlooking Melville Water on the Swan River. The southern aspect of the building and its general design will give every facility for microscope work. It is proposed to proceed next with the transfer of the departments of chemistry, physics, and agriculture before removing the arts faculty and the administrative sections from the present temporary buildings in the centre of Perth city. The engineering school is already on the permanent site, having been in 1914 in the Crawley Mansion House on the transfer of the estate to the University by the Government of Western Australia.

PROGRESS in home economics education during the years 1920-22 is described in Bulletin No. 6 of 1923 of the United States Bureau of Education. A general demand for retrenchment in school expenditure led to proposals in many parts of the country for eliminating home economics as well as music, art, industrial arts, and agriculture from school curricula, but a reaction speedily ensued accompanied by a marked stimulation of local interest in the teaching of these subjects. Meanwhile, the campaign for economy had improved the teaching of such subjects as cookery through necessitating the use of simpler and less expensive methods and extreme care in regard to the quality of the resulting products. One of the most admirable modifications of home economics courses was the devotion of increased time and attention to training young women in child care and welfare. This training has been linked with the food courses in high schools through individual pupils being made responsible in the later stages of their work for the nutritional condition of some younger child. The food courses have themselves been markedly changed, cooking processes receiving less, and nutrition and dietetics greater emphasis than formerly.

RECENT awards of Industrial Bursaries and Overseas Science Research Scholarships by the Royal Commission for the Exhibition of 1851 are as follows. The names of the nominating institutions are in brackets. *Industrial Bursaries:* J. M. Todd (University of Edinburgh), W. McCartney (Heriot-Watt College, Edinburgh), G. B. Hamilton and D. Murray (University of Glasgow), G. G. Forrest (University of St. Andrews), T. Etheridge (University of Birmingham), A. G. Oates (University of Bristol), F. Allen (University of Leeds), W. B. Noddings and E. R. Knight (University of Liverpool), G. Lindley (University of Sheffield), F. F. Ridley (University of Durham: Armstrong College), J. S. Wilson (University College, Nottingham), J. F. Smith, J. M. Radcliffe, and W. A. P. Fisher (University of Cambridge), P. C. England (University of London: King's College), W. E. J. Budgen (University of London: East London College), A. Taffel (University of London: University College), G. A. Bonnyman (Imperial College of Science and Technology), J. R. Rowlands (University College of North Wales, Bangor), A. R. Brown (University College of South Wales and Monmouthshire, Cardiff), O. G. Evans (University College of Swansea), A. Goffey, R. E. L. Tricker, and C. R. Smith (University of Manchester). *Science Research Scholarships:* J. F. Lehmann, Physics (University of Alberta), I. R. McHaffie, Physical Chemistry (University of Manitoba), W. L. Webster, Physics (University of Toronto), R. W. E. B. Harman, Physical Chemistry (University of New Zealand), L. H. Martin, Physics (University of Melbourne), F. Lions, Organic Chemistry (University of Sydney).

Societies and Academies.

PARIS.

Academy of Sciences, September 17.—M. Joseph Boussinesq in the chair.—The president announced the death of M. J. Violle.—P. **Villard**: The true colour of clouds. It is generally admitted that the true colour of clouds is white, and that the colour effects observed are due to the coloured rays of the sun at sunrise and sunset. From the results of twenty years' observations the author believes that this is not always the case and that clouds may possess a colour of their own, not necessarily white, although illuminated with pure white light. Variations of colour have been noted during the disappearance and re-formation of light cumulus clouds.—P. **Sergesco**: The distribution of the characteristic values of the nuclei of Marty $N(x, y) = A(x)K(x, y)$.—Antoine **Zygmund**: The Riemann theory of trigonometrical series.—Georges J. **Rémoundos**: A property of elimination and algebroid functions.—O. M. **Tino**: The passage from the theory of the fundamental Fredholm functions to that of the fundamental Schmidt functions.—Serge **Bernstein**: The mathematical demonstration of Mendel's law of heredity.—A. **Petot**: A characteristic difference between the modes of action of front and back brakes. It is shown that there is a fundamental difference between

the action of front and back braking on a motor-car. The latter arrests only the motion of translation of the car; in the former the brake also affects the car's movement of rotation round the vertical. —L. J. **Simon** and M. **Frèrejacque**: The action of dimethyl sulphate on salicylic acid, methyl salicylate, and methoxysalicylic acid. Sulphonation and methylation. In the absence of water, methyl sulphate and salicylic react, giving three substances, $C_6H_3(OH)(CO_2CH_3)SO_3H$, $C_6H_3(OH)(CO_2CH_3)SO_3CH_3$, and $C_6H_3(OCH_3)(CO_2CH_3)SO_3H$. The trimethyl sulphonated derivative is not produced.—Ch. **Courtot** and A. **Dondelinger**: Some new secondary bases of the indene series.—Paul **Dumanois**: A method of air-drying. A scheme for preventing the moisture in air reaching absolute alcohol or petrol stored in bulk. —F. **Vincens**: The aspergillomycosis of bees.— R. **Herpin**: Ethology and development of *Nereis caudata*.

SYDNEY.

Royal Society of New South Wales, August 1.— Mr. R. H. Cambage, president, in the chair.—S. **Dodd**: Cancer of the ear of sheep: a contribution to the knowledge of chronic irritation as a secondary factor in the causation of cancer in the lower animals. Cancer of the ear is rather common in sheep in Australia. Ears from 47 sheep so affected were examined microscopically: 32 were found to be definitely epitheliomatous; 9 showed a condition of chronic inflammation only, and 6 were in a precancerous stage. An affected sheep received alive was kept under observation; five months later the middle cervical gland showed signs of enlargement. Six months after receipt the sheep was killed and the autopsy showed practically the whole of the ear to be carcinomatous. The facts presented support the view that a chronic irritation, naturally occurring, may lead to cancer in the lower animals.—L. S. **Cash** and C. E. **Fawsitt**: The estimation of cineol in essential oils by the Cocking process. The method consists in mixing the oil with *o*-cresol in certain fixed proportions and finding the freezing point of the mixture. The method is more easily carried out than any of the other methods usually employed for estimating cineol. The results are at least as accurate as those obtained in other ways and the accuracy can be increased by taking into consideration the density of the oil.—H. J. **Hynes**: Investigations by the late C. O. Hamblin into the Helminthosporium disease of wheat. Pathogenicity tests indicated that the strain of Helminthosporium isolated from Marshall's No. 3 wheat at Cowra in November 1920 is a true parasite of the wheat plant, capable of causing a "Foot-Rot" condition and also lesions on the leaves. Seed from diseased plants when sown gave rise to healthy plants. The "Foot-Rot" condition was observed at Cowra in 1921 on 150 different wheat varieties. Spores of Helminthosporium were found on Slav rye, skinless barley, *Hordeum murinum*, *Bromus inermis*, *B. sterilis*, and spear grass.

Diary of Societies.

MONDAY, OCTOBER 15.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. Shattock: Necrosis.

INSTITUTE OF MARINE ENGINEERS, INC., at 6.30.—Extraordinary General Meeting.

TUESDAY, OCTOBER 16.

ROYAL SOCIETY OF MEDICINE, at 5.—General Meeting.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—J. G. Marshall: The Back Page of a Newspaper.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Prof. E. Newberry and others: Discussion on The Origin of Cultivated Plants.

WEDNESDAY, OCTOBER 17.

ROYAL METEOROLOGICAL SOCIETY, at 5.—Discussion on a paper by Sir Napier Shaw and Capt. D. Brunt: Towards a Basis of Meteorological Theory—Thirty-nine Articles of Condition for the Middle Atmosphere.

ENTOMOLOGICAL SOCIETY OF LONDON, at 8.

ROYAL MICROSCOPICAL SOCIETY, at 8.—W. F. Charles: Peculiarities in the Development of the Ant's Foot.—M. T. Denne: A New Variable Light Screen for Use with the Microscope.—Prof. Ekendranath Ghosh: Monocystides from the Earthworms of Calcutta.

THURSDAY, OCTOBER 18.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at 5.30.— Squadron Leader R. M. Hill: The Manœuvres of Inverted Flight.

CHILD-STUDY SOCIETY (at Royal Sanitary Institute), at 6.—Dr. F. S. Boas: Some Aspects of the Departmental Report on English.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—Dr. A. Russell: Presidential Inaugural Address.

CHEMICAL SOCIETY, at 8.—R. G. W. Norrish: Studies of Electrovalency. Part III. The Catalytic Activation of Molecules and the Reaction of Ethylene and Bromine.

SOCIETY FOR CONSTRUCTIVE BIRTH CONTROL AND RACIAL PROGRESS (at Essex Hall), at 8.—Dr. Marie Stopes: Medical Contradictions and Mistakes in Evidence in her Recent Case (Presidential Address).

FRIDAY, OCTOBER 19.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: Hernial Formations of Developmental Origin which occur along the Alimentary and Respiratory Tracts.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir John Dewrance: Presidential Address.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—A. Pereira: In a Kinema Studio.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—F. W. Dye: The Gas Boiler (or Circulator) and its Application.

PUBLIC LECTURES.

SATURDAY, OCTOBER 13.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Capt. W. H. Date: Wireless Telephony—a Popular Exposition.

UNIVERSITY COLLEGE, LONDON, at 5.—Miss I. C. Ward: The Application of Phonetics to the Curing of Speech Defects.

TUESDAY, OCTOBER 16.

UNIVERSITY COLLEGE, LONDON, at 5.30.—Prof. A. V. Hill: The Present Tendencies and Future Compass of Physiological Science.

GRESHAM COLLEGE, at 6.—Sir Robert Armstrong-Jones: Physic. (Succeeding Lectures on October 17, 18, and 19.)

WEDNESDAY, OCTOBER 17.

UNIVERSITY COLLEGE, LONDON, at 3.—Prof. E. G. Gardner: Problems of the *Inferno* (Barlow Lectures). (Succeeding Lectures on October 24, 31; November 7, 14, and 21.)

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—A. Greenwood: Cancer and the British Empire Cancer Campaign.

KING'S COLLEGE, LONDON, at 5.30.—Prof. A. Dendy: The Biological Foundations of Society. (Succeeding Lectures on October 24, 31; November 7, 14, 21, 28; December 5 and 12.)

THURSDAY, OCTOBER 18.

KING'S COLLEGE, LONDON, at 5.30.—Prof. J. A. K. Thomson: The Function of Scholarship.

SATURDAY, OCTOBER 20.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Tutankhamen and his Times.

Scientific Papers and Books.

"Of making many books there is no end; and much study is a weariness of the flesh."

ONE of the problems which scientific investigators have to face is that of the great mass of literature with which they are supposed to make themselves familiar before they proceed along the road in which their interests lie. It is almost impossible in these days to keep in touch with everything published, even in a single department of science, by all the scientific societies and institutions of the world; and the result is that the announcement of an interesting observation or experiment is frequently followed by a claim for priority from another worker in the same field. Creative work of the first order is of course very rarely anticipated in this way, but determinations of properties, measurements of values, observations of structures, records of particular effects, and so on, are often duplicated and sometimes lead to discussions into which unworthy imputations are introduced.

Such publications as the International Catalogue of Scientific Literature and the Royal Society Catalogue are useful as guidance to what has been published on various subjects or by different workers, and several scientific societies publish collections of abstracts periodically, while the excellent Subject Index to Periodicals issued by the Library Association provides a means of ready reference to the titles of many papers worth attention. These and similar aids cannot be neglected by investigators engaged in original scientific work unless they are indifferent to what has been done, or is being done, by others in the same field. It is said that a government official who had been largely responsible for securing a grant for the International Catalogue of Scientific Literature once asked a distinguished man of science whether the Catalogue was very useful, and was astonished at the reply: "I do not know, because I have never used it." Few people engaged in research are, however, so original that they can afford to take this risk; for, like wise inventors, they realise that unless they know what has already been produced they may waste much valuable time in doing something for which no claim for originality can afterwards be substantiated.

The numerous original papers which reach NATURE office every week in publications of societies and as separate reprints, afford us an idea of the difficulty in which every scientific investigator must find himself. We cannot attempt to do more than mention a few points of prime importance or wide interest selected from these papers; for merely to give the titles of them all would occupy several pages every

week. Every paper received is, however, sent to a contributor familiar with the general subject and not likely, therefore, to overlook anything of outstanding importance. Our columns of Research Items, and short articles which follow them, represent the result of such eclectic surveys of a body of literature which increases in volume every week, and from which limitations of space permit only a few specific points to be described. Nothing more can be reasonably expected in a general scientific newspaper such as NATURE, the main appeal of which is to the scientific world as a whole and not to a specialised section of it.

It is even more difficult to decide how to deal with the great mass of scientific books now published than it is with papers. Within the past four weeks, for example, we have received no less than 150 volumes, almost all of which have distinct characteristics and many of which merit extended notice, on account either of the positions of the authors or the interest of the subjects. It is obviously impossible, however, for us to review more than a fraction of these volumes without destroying the balance and the character of our columns. Our monthly list of Recent Scientific and Technical Books includes bibliographic details of every book received, as well as of others, and this should serve as general guidance to the various works being issued on scientific subjects. By publishing all these titles we are able to do for books what it is impossible to undertake for single papers or memoirs.

As regards reviews, experience shows that those of the essay type, which deal with the subjects of the books broadly and descriptively, are most widely read, and therefore serve the best purposes of both author and publisher. Summaries of the contents of the various chapters of a book, with comments upon them, are more appropriate in prospectuses and advertisements than in the columns of a journal which aims at interesting its readers in the progress of science generally, and not alone in the special portion of the field in which they are themselves working. A review should, however, be a judgment as well as a description; for readers are guided by it in their decision whether to add the book to their libraries or not. Differences of temperament are sometimes responsible for the same volume being praised by one reviewer and condemned by another of equal authority. Some reviewers are always kind, while others are always critical, looking for faults rather than for points worthy of commendation. To this class belonged the reviewer who concluded his notice with the words "We have not found any mistakes, but no doubt there are some." If a book contains a large number of errors, probably the best plan is to neglect it altogether. We prefer not to print lists of such errors, but to send them to the author or publisher, who is always grateful to know of necessary corrections of this kind.

The authors who are never satisfied with the treatment which their works receive are those who evolve elaborate theories, or assert new principles, without sufficient knowledge to understand how untenable their views are. If their works are not noticed, authors of this type nourish the grievance that there is a conspiracy of the scientific world against them. It is useless to publish a short notice stating that the work has no scientific value or is fundamentally unsound. What such authors expect are discussions in detail of the points they raise, though no one else would be likely to be interested in such discussions.

From our point of view, the size of a book affords no standard of the space which may appropriately be given to it. Interest of the subject and distinction of the author are the chief claims to attention. A slender volume may thus be more worthy of extended notice in the form of an essay review than one of a thousand or more pages. With the best intention in the world, however, space cannot be found for adequate notice of all such works now published. Necessity, and not inclination, determines what can be dealt with in this way, and from the rest it is only possible to select some for notice in our Bookshelf columns. What we particularly desire authors and publishers to understand is that the sending of a book for review creates no obligation to publish a notice of it. All that we can undertake is to examine the book and to send it to a reviewer with an invitation to contribute a review of a prescribed length, or to include it in a parcel of books with a request to select a few of the best for notice. The rest appear only in our monthly lists.

Even with these limitations, the congestion of reviews and minor notices is always severe, and we are never able to outrun the flood of literature which continually threatens to overwhelm us. It would be easy to publish every week an equal number of reviews and other notices to that included in the present issue, and yet not exhaust the pile of books which merit consideration. Critical minds may deplore this abundance of printed pages, but to us it seems that most of the books have some original characteristics of style, substance or treatment, and we must confess to a feeling of sympathetic regret for the authors whose works have often to be dismissed somewhat summarily, purely on account of considerations of space. They should be as grateful as we are that leading workers in all branches of science are willing to examine books carefully, and to make some of the volumes subjects of such interesting and useful notices as those which continually appear in the columns of NATURE, and are represented by the reviews included in the present issue.

The Scope of Science.

The Domain of Natural Science: the Gifford Lectures delivered in the University of Aberdeen in 1921 *and* 1922. By Prof. E. W. Hobson. Pp. xvi+510. (Cambridge: At the University Press, 1923.) 21*s*. net.

DR. HOBSON'S important book falls into three main divisions: the first consists of four lectures and describes his general philosophical position, or rather, as he would prefer us to say, his view of the nature of science and its relation to philosophy; the second, being in fact the bulk of the book, comprises fourteen chapters, giving a survey of the development of scientific thought in all its main branches from mathematics to biology; the third, which is a sort of epilogue, brings the book within the terms of the Gifford Trust and deals with the limits of natural science and religion: this is the last two chapters. We will say a few words about each in turn.

Dr. Hobson's general view of the nature of science agrees with that of Mach and Karl Pearson. He explains it carefully and frequently, and arranges the main substance of the lectures so that they depend on this thesis and illustrate it. In this view a scientific theory is "a conceptual scheme, designed by the synthetic activity of the mind, working with the data of perception, for the purpose of representing particular classes of sequences and regularities in our percepts." It has nothing to say as to the reality, or non-reality, of anything behind phenomena, nothing as to efficient or final causes. It is an intellectual shorthand, enabling mankind to deal more and more economically and effectively with the facts of perception which crowd in upon us.

Dr. Hobson is very careful to remind us of the implications of this point of view at every turn in his argument, and it is especially congenial to his own mathematical mind. For this reason he has been able to give us an exposition of the doctrine, quite unexampled in England, if not abroad. Mathematics obviously illustrate the thesis best, and he shows us, *e.g.*, how in dynamics the failure sharply to distinguish the conceptual statement of scientific laws and theories from statements as to percepts has obscured the true nature of science. We can speak and think clearly about a conceptual body moving in conceptual space according to definite numerical specifications, whereas there is no meaning in the assertion that a body moves uniformly in a straight line in physical space. In the same way Dr. Hobson quite rightly treats Einstein's theory of relativity as a conceptual correction of the Newtonian conception: not as a revolution and, above all, not as a new philosophy.

It was certainly a happy thought on the part of the lecturer to turn his general argument into a sort of generalised history of science, and a happy liberality on the part of the Gifford Trustees which enabled them to include it within the corners of their scheme. Histories of science are much in the air just now, and we are constantly seeing small popular books issued on some aspect of the subject, generally biographical. Here we have a survey by a master of the fundamental science of all, who has for years interested himself in general scientific development, and applies an acute, impartial and cautious mind to a statement and an estimate of all the leading theories, especially the more recent, in physics, cosmology and biology. It is a most careful and substantial work which will be of the greatest service to future toilers in the same field. For between the popular histories and the specialist and the philosophical—of which this is an eminent example—there is still a gap waiting to be filled by a concrete, lively, up-to-date survey, such as Mrs. Fisher attempted in the 'seventies and 'eighties.

Dr. Hobson's survey requires careful reading, as it has arisen from careful and thorough thinking and writing. He passes from weighing and delimiting the determinist physical schemes of science to a similar comparison and estimate of dynamical theories. From this to a discussion of the conservation of matter and energy, a sphere which gives him scope for penetrating application of his general theory. What is to be understood by the statement that matter can be neither created nor destroyed? If we mean a substratum, substance itself, not identified with any physical properties, but the bearer of them, we remove our principle from all possibility of verification and make it a bare philosophical assertion with no direct relation to the world of percepts, outside the domain of natural science.

This discussion is followed by a full account of the recent electrical theories of the nature of matter and of the various manifestations of radio-activity. Two chapters discuss cosmical theories and Einstein; four, biology in general, the living organism, heredity, and the evolution of species. In all, the same balanced judgment is maintained, with the same readiness to keep and inculcate an open mind towards the indefinite expansion of scientific truth. Thus, while not accepting the adequacy of any determinist scheme at our present stage of thought, we are not to consider that there are any barriers which will prevent "even larger tracts of phenomena from being correlated with deterministic descriptive schemes." In the realm of life, while allowing full force to the contentions of Driesch and the Neo-vitalists, he tells us that we must be prepared to contemplate as a possibility that the ultimate

answer to the question, "What is the distinction between living and non-living matter?" will be that, within the categories of science as here expounded, there is no final distinction.

One is not surprised to find in the application of this theory of the nature of science to the question of religion, or rather of theism, in the two concluding chapters, that Dr. Hobson's attitude is frankly, completely and impartially agnostic. He examines the various forms of theistic belief very briefly and points out their difficulties. He also—and this is perhaps the most valuable part of this section—indicates the change which has taken place in the line of defence in recent times. In pre-Kantian times the defenders of theistic theories based them on evidences of design, on the objective universe. This Dr. Hobson dismisses with the remark that those who argued from the mechanism of the world to a Great Mechanic forgot that the watchmaker has his material supplied ready to hand: his design consists in the adaptation of the given material to his own idea. The Great Mechanic of the universe has to supply his own material, and it is precisely in understanding the origin of the material itself, the life itself, that the supreme difficulty lies. The more recent arguments from design arise from the purposive activities, the entelechy as Driesch names it, of particular organisms, not from a general purpose in the universe as a whole. The arguments which now appeal most to mankind—apart from these purposive activities of individual living beings—are the need of a Universal Rational Mind to justify and act as a basis to the general intelligibility of the universe; and the moral argument, that we need the conception of an Ideal Being to supply the notions of value towards which mankind is always striving, and which he does not find in the humble origins of life towards which scientific research is constantly pressing him. This latter attitude dates in its modern prominence from the work of Kant. On the former our author aptly quotes from Dr. Rashdall: "We cannot understand the world of which we form a part except upon this assumption of a Universal Mind for which, and in which, all that is exists. Such is the line of thought which presents itself to some of us as the one absolutely convincing and logically irrefragable argument for establishing the existence of God."

Here Dr. Hobson leaves it, being content in this part of his argument, as in the rest, to state the rival positions which he considers either that science has not yet conquered, or that do not properly belong to science at all. For his own view of science, as a man-made scheme bringing together, clarifying and co-ordinating our percepts for our own convenience of thinking and applying our thought to action, a purely human synthesis is quite sufficient. The perceptual domain is such that whole tracts of it, and processes in it, are capable of description by rational schemes; and these schemes are so far justified by successes in the past that we can see no limit to their extension in the future on the same lines. These lines are, truthful observation, the simplest hypothesis which co-ordinates the facts and verification by a subsequent return to Nature. The progress which man has made in framing such schemes so far surpasses what he has achieved either in ordering his surroundings or improving his own nature, that we are justified in treating it as the index of his advance. It was the most remarkable and permanent achievement of the Greeks. Its return in the sixteenth century marks the beginning of the modern world. Its dominance in the present age confronts us with our most serious problems and inspires us with the strongest source of hope for their solution.

F. S. Marvin.

A Reconstruction of Polynesian Culture.

The Belief in Immortality and the Worship of the Dead. By Sir James G. Frazer. Vol. 2: *The Belief among the Polynesians.* Pp. ix+447. (London: Macmillan and Co., Ltd., 1922.) 18*s*. net.

In Polynesian mythology the god Maui, fishing in the waste waters of primeval chaos, hauls up the island world at the end of his line. It requires no less skilful a fisherman to bring up again the Polynesian world of savage life and custom from the chaos of insufficient and scattered data embedded in travellers' and missionaries' records. Sir James Frazer, by the present volume, deserves to take his rank beside the primeval fishers—though his work of rescuing a world in dissolution must have been much less joyous and probably more difficult than that of the earlier sportsmen. Those who know the immense difficulty of extracting truth from amateur ethnographic material, and of giving it scientific and literary form, will be able to appreciate the industry and genius contained in this latest contribution of Sir James Frazer.

There is probably no more fascinating chapter of ethnography than the life and customs of the Polynesian islanders, as they were before European contamination. The present volume is the best all-round picture of Polynesian life available, for here, as in his other books, Sir James Frazer gives more than he promises. The title indicates that the research will be concerned with native beliefs in immortality and with the worship of the dead. In order not to tear the subject out of its context, however, Sir James describes the Polynesian ideas of the next world against the background of their religious and magical

creeds, and these again he places within the setting of tribal life, not forgetting to give us a picture of the physical environment.

Thus, in one archipelago after the other, we receive a vivid though fleeting vision of the lofty volcanic peaks, the forest-clad slopes, and the shaded coral beaches where clearings, smoke, palm plantations, and gabled roofs indicate the sites of villages. We are then led over the settlements, shown the eager gardeners and the skilled fishermen at work, the talented and industrious artists carving and decorating various objects with their fantastic designs, the indefatigable manufacturers weaving mats, shaping and polishing stone implements, building canoes, and erecting huge houses. They are doing all this, in pre-European times, with the aid of stone implements only, without the help of any metal. We see the adventurous sailors setting out on some distant expedition, whether as a semi-religious, semi-dramatic company of wandering performers in the Society Islands, or as a formidable raiding party in Samoa, or as a trading expedition from Tonga to Fiji. We are shown some of the strange and licentious customs of the South Sea Islanders, where a natural exuberance and a touch of artistry redeem them of their cruder features. The ceremonial and festive life of the islanders, culminating in the Areoi performances of the Otahitians, is recorded here in a very complete manner, and the critical caution and constructive talent of Sir James allow us to learn all that is genuine and true about these institutions of which much must, alas, remain for ever a mystery.

It is impossible to summarise briefly this masterly account of Polynesian civilisation, giving due consideration to the differences as well as to the similarities between its various branches. The great uniformity of this culture is indeed remarkable in a people scattered over a wide area in small and isolated communities. Linguistically they are so alike that one must speak, as Sir James does, of one Polynesian language with dialectic varieties. In social organisation they show a remarkable uniformity in structure, with their permanent village communities, with the simple system of kinship terms and the institution of social rank, hereditary and hedged round with taboos and ceremonial observances. Rank gives also political power in a highly developed chieftainship or kingship carried almost to deification. In economic pursuits they are similar, cultivating the same staple plants (taro, sugar-cane, bread-fruit, kava, and palm), and showing the same gaps and developments in arts and crafts.

But, for the student, the differences between the various Polynesian branches are quite as important as their similarities, and the present volume will be of special value and interest just because it does not lump all Polynesians together, but gives a series of monographs, on the Maoris of New Zealand, on the inhabitants of the Tonga archipelago, on the Samoans, the Hervey Islanders, the Otahitians, the Marquesans, and the Hawaiians.

In each chapter, the local beliefs in immortality occupy a dominant position, though always kept in proper proportion within the general picture. It would be useless to summarise each type of Polynesian afterworld. Like their customs and institutions, like their decorative art and mythology, the paradise of these natives is at the same time fantastic and beautiful, quaint and romantic. Born of hope and fear and human presumption, as all such beliefs are, it is a dreamland built up on the pattern of this life, improved and yet formidable, attractive and yet never really desired.

There is no doubt that the beliefs in human immortality, together with the fear of the dead and the hope of their beneficent intercession in earthly affairs, have been among the most important moulding forces of human religion. The chronicles of these beliefs, ranging over the whole world and over all levels of civilisation, which Sir James Frazer is now giving us in one volume after the other, will rank among the most important documents for the study of comparative religion. For the present, Sir James, engrossed in the quest of the immortality of all the peoples of the world, seems to be oblivious of his own: in this descriptive volume, as in the previous one on Australia and Melanesia, he wisely resists the temptation to put forward brilliant theories and daring hypotheses. But those who know Sir James's method realise that before framing any theory he has to study the facts, to collect world-wide material, and examine it by the comparative method. Collected with the author's width and depth of outlook, with his unrivalled grip of sources, and his genius for an all-round presentation, it is given out to scholars, who will thus have before them all the facts bearing on this problem of highest importance. But all anthropologists hope, of course, that there will come a last and crowning volume in this series, in which, as in the fourth part of his "Totemism and Exogamy," Sir James will develop another of his theories which have so greatly influenced modern humanistic thought.

The Rise of Civilisations.

The Cambridge Ancient History. Edited by J. B. Bury, Dr. S. A. Cook, F. E. Adcock. Vol. 1: Egypt and Babylonia to 1580 B.C. Pp. xxii + 704 + 12 maps. (Cambridge: At the University Press, 1923.) 35*s.* net.

THE most valuable and scientific part of this work is the first sixth of the volume, by Prof. Myres, which is an elaborate correlation of Tertiary geology,

climate, conditions of life, and movements of races. Though the detail might be gleaned elsewhere, the realisation of the manner in which each change conditions others, the presentation of the continuity of this pre-history, and the living sense of the realities of existence, put plainly to the reader the complexities of tracing the history of man. Such a mass of detail cannot be at all a final statement; the knowledge that has been gleaned in the last fifty years is much too fragmentary as yet. We can welcome this as a piece of courageous charting, which will show where the blank places lie, and make us realise the value of scattered items which may be fitted into place.

Above all, Prof. Myres has the historical sense which is needed for success in interpreting the facts of anthropology and archæology. His attitude about some essential matters may be noted. He accepts fully the production of skull form and features by conditions of food and life, yet also accepts the racial character of skulls. The waiting problem is that of the time required to alter racial types under different conditions; this is not touched on here, for the good reason that there has been no general study of it as yet, although it is at the basis of anthropology. He accepts the unity of European and Mediterranean changes of level in glacial times; and he takes the longer scale of human relation to glacial epochs, as according better with evidences from the Nile. He regards the Mousterian work, of the third glaciation, as having been annihilated by the Aurignacian people arriving from the S.W. The Solutreans he accepts as coming from the N.E. steppe, perhaps derived directly from Acheulean workers, and flowing across Europe, forming the earliest people of Scandinavia, passing down into Egypt, and also southward to Susa. Thus the unity of culture in these regions is accepted. The Capsian was a ruder style, originating in North Africa and pushing up as far as Belgium, leaving kitchen middens, which point to a communal habit. The Magdalenian people are regarded as only an Atlantic branch of the Solutrean in a harsher climate; but the appearance of that type of work in Egypt seems to show that it was not so local, and would be due to a definite movement of a people.

Coming to later times, the Highland or Alpine people are postulated as extending over all the mountainous region from Armenia to France. When we look at the various races already pushing about in the world, it would be incredible that along two thousand miles of unfavourable country one race should persist without spreading down into better lands on both sides. The type is here derived from the food conditions of a forest people who lived mainly on fruits and roots. The principle of skull type being conditioned by climate and food seems the only explanation of the similarity of Alpine people, and we may talk of an Alpine type, while by descent the people might belong to a dozen different races living in the neighbouring plains. This mountain life appears to confer dominant qualities on the people, when mixed with other races. The so-called Armenoid is supposed to have come from the Asia Minor plateau; but if the type depends on mountain life, why should it not equally have grown in the Lebanon or North Syria?

The supreme value of pottery as archæological evidence is lovingly expounded in two pages, after which there is a careful account of the Lake culture, the Danube peoples, Anau and Susa, the Mediterranean culture, the Beaker folk, the Bronze users, and the Halstatt age, explained by several original maps. This work has laid down the first stage of a science, by forming a continuous and consistent scheme of the whole, by which each fresh detail found will have its value as confirming or correcting this framework of our conceptions.

The other chapters which deal with the age of artistic and written records are sound statements of what is now known, and accessible in other works. The most original parts are on the early Babylonian, by Prof. Langdon, and on the early Aegean, by Mr. Wace. In a volume so crowded with detail there must be many differences of opinion, which it is impossible to note here. The treatment of historical material in general does not freely sacrifice it to the internal consciousness of the German school. We may note in passing that glass was not an Egyptian invention, but was very rarely introduced from some outside source during thousands of years, before it became suddenly very common after the conquest of Syria, 1500 B.C. Glaze was known from the earliest prehistoric age in Egypt, but it is not likely to have been invented by that culture. The long priority of Sumer and Elam before the civilisation of Egypt is well stated by Prof. Langdon.

However much work the writers have put into this book, they have been crippled by the editors not allowing illustrations. The ideal of the publication is far too literary. Even the age of Acts of Parliament needs some material representations to understand it, and to write of times in which the whole evidence is material, without using any illustration, is dancing in fetters. It would be as practicable to write of palæontology without a figure of a fossil, or of geometry without a diagram. The salvation of this work would be to issue an explanatory volume of small figures of everything named here, and in a second edition put in numbered references to the figures.

W. M. F. P.

The Genetics of the Fowl.

Heredity in Poultry. By Reginald Crundall Punnett. Pp. xi + 204 + 12 plates. (London: Macmillan and Co., Ltd., 1923.) 10*s*. net.

MODERN genetics is founded in great measure upon the results of experimental breeding work with material which, in the opinion of the average stock-breeder, cannot be regarded as a "real" animal. To him, *Drosophila melanogaster*, and all that pertains thereto, is far too remote to have any bearing upon the peculiar problems of the man who raises stock for profit. He does not understand why Drosophila is unique as genetic material. The experimental biologist must have an animal with few and heteromorphic chromosomes; it must be easily and cheaply kept under laboratory conditions; it must exhibit a very varied characterisation and it must breed rapidly, producing large numbers of offspring in each generation.

It has to be confessed that to the breeder of pedigreed stock, the geneticist has but little to offer that can be applied with profit to the art of breeding specimens of the established breeds—and this is the occupation of the most successful breeders. The breeder has drawn up his own standards of excellence, usually in absolute ignorance of the scientific principles which undoubtedly underlie his art, often indeed in direct defiance of these principles, and has set himself the task of attaining them. In many cases he has succeeded, and it may be accepted that the success of the makers of the modern breed of domesticated animals must have been achieved by methods which were not violently in discord with the principles of heredity which have been disclosed comparatively recently by the geneticist. But these principles were in operation long before the geneticist discovered them, and it was not to be expected that their discovery would result in any profound modification of the breeder's practice. Certainly, the science of genetics can offer to the breeder of pedigreed stock the means of interpreting his successes and his failures, but it is to the creator of new breeds, to the improver of the old, that it can promise most. It can offer more to the breeder of highly fertile, quickly-reproducing stock than to the breeder of cattle or sheep.

Moreover, since at the present time almost the entire weight of the modern chromosome theory of heredity is carried by the dipteran Drosophila, the British geneticist is seeking other suitable experimental material. The organisation of the National Poultry Institute has provided him with a unique opportunity of employing the fowl: there can be no better material for the geneticist working in a research institution, the function of which is to aid the breeder in the solution of his problems. Research is being more and more concentrated in institutes, and above their doors the slogan "Knowledge for its own sake" is not inscribed. In such institutes it is necessary to use material with which the community at large is acquainted, so that its co-operation may be secured, and after all, the study of the phenomena of inheritance in the fowl is equally as thrilling as that which centres around Drosophila. The geneticist cannot readily aid the fancier who is dealing with characters so fine that from the point of view of genetics they demand an outlay in expenditure and meticulous attention by no means commensurate with the theoretical value of the results likely to be obtained; but his interests coincide with those of the utility poultry man who is eagerly demanding knowledge of the mode of inheritance of such characters as fecundity, broodiness, egg-colour, and fertility. The geneticist can, in using the fowl as his material, add considerably to our knowledge of the principles of heredity, and at the same time can bring much-needed assistance to a most worthy section of the community.

Indeed it was with the fowl that Bateson, more than twenty years ago, first showed that the principles enunciated by Mendel, then newly discovered, applied to animals as well as plants. It is certain that had the work of Bateson and Punnett, which immediately followed this, been properly appreciated and adequately financed, the present position of British genetics and of the science of genetics applied to animal breeding would have been very different to-day. It is true that Prof. Punnett has been carrying out experimental breeding work with poultry for twenty years, and that, as his book indicates, he has made most valuable contributions to our knowledge of the genetics of the fowl; but what he has done is but a fraction of what he could have done, had he not been embarrassed by insufficient material and inadequate accommodation.

It seems that at last Prof. Punnett's difficulties are to be removed, for under the auspices of the National Poultry Institute he is to be given the opportunity of carrying on his work under satisfactory conditions. At one time it seemed as though the scheme would fall through, for the response to the appeal for subscriptions towards the funds of the Institute was somewhat tardy. His book appeared most opportunely and greatly strengthened the appeal of the leaders of the poultry industry in England. It showed clearly what had been done by the geneticist working under difficulties, and provided a vision of what could be done when these difficulties were removed. Its reception by the poultry breeders of the country provided an

indication of the eagerness with which the "practical" man is turning to the man of science for information. To the poultry-breeder this book is indispensable, for it gives a concise picture of all that has been done by the geneticist working with poultry up to the end of 1922, and no poultry-breeder can afford to disregard the facts with which the book is crammed. To the biologist the book will have a different interest: it will serve as a landmark in the history of the genetics of the fowl, for in the next decade great advances are due. In America, in Australia, in Russia, and in Britain, much concentrated experimental breeding work is in progress. The phenomena of linkage are now being investigated, but owing to the greater complexity of the chromosome constitution—there are seven large pairs and at least nine small pairs of chromosomes, it appears—it cannot be expected that progress will be as rapid and spectacular in the fowl as it has been in the case of Drosophila. To those of us who are working with the fowl this book is a great stimulus: Prof. Punnett's 1933 edition shall bear witness to what the geneticist can do, given opportunity.

F. A. E. C.

Essence and Existence.

Scepticism and Animal Faith: Introduction to a System of Philosophy. By George Santayana. Pp. xii+314. (London, Bombay and Sydney: Constable and Co., Ltd., 1923.) 12*s.* net.

The Life of Reason: Or the Phases of Human Progress. By George Santayana. Second edition. In 5 vols. Vol. 1: Introduction and Reason in Commonsense. Pp. xix+291. Vol. 2: Reason in Society. Pp. viii+205. Vol. 3: Reason in Religion. Pp. ix+279. Vol. 4: Reason in Art. Pp. ix+230. Vol. 5: Reason in Science. Pp. ix+320. (London, Bombay and Sydney: Constable and Co., Ltd., 1923.) 8*s.* net each vol.

MR. SANTAYANA has a wonderful gift of expression and writes with a distinction and charm which are an unending source of delight. Yet he leaves his readers with a strange unsatisfied feeling not free from a touch of resentment. He is a true poet, who can write prose with all the rhythm of verse. Born in Madrid of Spanish parents, he tells us that he has chosen our language for his literary expression, though it is not his native tongue, because he considers that so far as containing truth is concerned one language is as good as another, and he prefers ours. Also, what is truly admirable in a philosopher, he finds it adequate. When we read, however, his sustained but pleasant and well-balanced soliloquising, we cannot but wonder why he should suppose that we are interested in his want of interest in what interests us. Yet this is the whole burden of his philosophy.

Mr. Santayana told us in a recent book that when the War came it found him at Oxford, and he remained there, apparently because he could look on without taking part, indifferent to the result, and comparatively undisturbed. He was content to leave the issue to the statesmen and soldiers; the folly and the wickedness of it might sadden him, but his care was that it should not attach him or invade his philosophic calm. In the same spirit he now contemplates the scientific revolution in mathematics and physics which has produced in our time an intellectual upheaval. It interests him, of course; he thinks it may mean that he is living to see the emergence of a new concept of nature, a new cosmology, comparable with those of Heracleitus, Pythagoras, or Democritus, but as a philosopher he has no part in the matter, and the issue, whatever it be, will not disturb him. He glories in the fact that he does not understand the new principle and is easily and comfortably warned off the attempt to understand it. He knows he has not the technical equipment of the mathematician, and so he must and will accept the new discovery whenever the mathematicians and physicists tell him they are agreed.

It is possible there are many students of science who will heartily approve this maxim of the aloofness of philosophy from all actual scientific research. It seems to express exactly what the great scientific leaders of the nineteenth century were always insisting on, the positivity of physics, the speculative nullity of metaphysics. Gladly will they respect the moralising, soliloquising, mysticising philosopher, especially if, like the author we are considering, he be endowed with poetic genius, so that he will not interfere with the stern experimental work in which science is engaged. But if that ideal would suffice for the last century it fails utterly to satisfy the present. The coming of the theories of relativity has changed the whole aspect of the scientific world and the whole attitude of men of science to philosophy and of philosophers to men of science. Science and philosophy are now engaged in a conjoint undertaking, the adaptation of the human mind to a new cosmogony forced upon it by the necessity of fitting experimental facts into natural conceptual frames.

What then, in the present state of our science, has Mr. Santayana to tell us which is positive? What is the substantive part of his contribution? He has something very definite to say, and whether he knows it or not, and whether he cares that it should be so

or not, it proves to be singularly in accord with the significance and direction of the new scientific theories. He tells us he is a materialist, but adds that it may be he is the only philosopher who is. All that this seems to mean is that, with Spinoza, he seeks the unity of the world in an objective and deterministic principle rather than, with Leibniz, in a subjective and creative principle. He is no more materialist in the ordinary acceptation of the term than Spinoza is atheist. His theory, however, merits the attention of experimentalists.

His theory is that "existence" is not a datum. We can have no image of it and no idea of it. We accept it with "animal faith." What is "given" to the mind in knowledge is not the *existence* of objects but their *essence.* This is true of the mind itself, of the *cogito ergo sum,* equally with the objects of the physical world. Essence is not a subjective eject: it is objective in the fullest meaning of the term. This rejection of existence as a datum is of special significance in philosophy, for it serves to separate Mr. Santayana from the realists with whom his "materialism" would seem naturally to associate him, from those who, like Prof. Alexander and Prof. Lloyd Morgan, insist on the importance of assuming the existence of the non-mental world, even though it may need to be accepted "with natural piety." But it is of peculiar significance in science; for if Einstein and the orthodox relativists are right, science has no longer any use whatever for this relic of an older world-view and its pious preservation is a superstition. Santayana's doctrine therefore, which does not reject existence but denies that it is a datum and excludes it from knowledge, is singularly in accordance with the theory that in physical science we are not contemplating absolute existence but co-ordinating phenomena by means of invariants. The "animal faith" which makes us believe the existence of a datum is not the philosophising will to believe or reason for believing: it is the ordinary man's intuition or instinct.

What then is essence, or rather what are the essences, which Mr. Santayana presents as the objective reality of things known? To the philosopher it is perhaps enough to say that they are the Platonic Ideas interpreted in a modern way, a concept which recalls Croce's æsthetic images, except that essences are not the creations of a *fantasia,* or the expressions of intuitions, but passively discerned objects. We are more interested, however, to know what is their status in science. They are, we are told, the indispensable terms in the perception of matters of fact and they render transitive knowledge possible. They are distinguished therefore from "bits of sentience" or pure sense-data, on one hand, by their external reference and from existents or pure existences, on the other hand, by their relatedness. The value of the doctrine to science is then that it takes us behind all such philosophical distinctions as primary and secondary qualities, universal and particular ideas, abstract and concrete terms, giving us at once what is ultimate in the reference to reality. Mr. Santayana takes as an illustration the colour quality "yellow." I may see a buttercup, the intuition is then a sensation; or I may see it with my eyes shut, it is then an idea or a dream; or I may see it with my eyes open when there is no buttercup there, then it is hallucination. Whatever be the difference in the mode of apprehending or in the object of reference, the essence yellow is one and identical.

To see the relevance of this theory to scientific research we have only to recall the endeavour of Mach to construct science out of the relations of sense-data. Mach found he had to fall back on a quite arbitrary hypothesis of parallelism. How different his task might have appeared had he had this conception of essence. His difficulty was to get to existence, and this demands belief. If, on the contrary, with Mr. Santayana, we start from the realm of essence, which demands no belief, we may at once find conclusive reasons for believing that sundry intuitions of parts of it exist in fact. This discrimination of essence brings too a wonderful clearness to the comprehension of the nature of scientific research. All data and descriptions, all terms of human discourse, are essences, inexistent. Existence is an intuition, inexpressible, not knowledge but ignorance, a purely animal faith. The distinction cuts science free from all the perplexities and antinomies which arise when reality is identified with existence (*e.g.* the non-existence of the past and future, the inextensiveness of the present).

Having expounded this important distinction of essence and existence, Mr. Santayana then proceeds, somewhat to our surprise and with at least the appearance of complete inconsistency, to select from the essences the philosophical concept of substance and the naturalist concept of matter to be the foundations of his new Jerusalem, a system of philosophy which we are led to expect is shortly to appear. We look forward to it with deep interest, for the present introduction shows him inspired with a new vision and emboldened to undertake constructive work. His book closes with a critical epitome of the history of modern philosophy in which, except Spinoza, each leading philosopher is pelted with epigrams, and ironically dismissed.

H. Wildon Carr.

Evolving Biology.

Outlines of Evolutionary Biology. By Prof. Arthur Dendy. With Glossary of Technical Terms. Third edition, revised and enlarged. Pp. xliii+481. (London: Constable and Co., Ltd., 1923.) 16*s*. net.

WE extend a welcome to this revised and enlarged edition of an exceedingly useful book, which has been a favourite since it was first published some ten years ago. It is an introduction to the study of the principles of biology, well thought out by a teacher of experience, who has himself made important contributions to the science. There are five parts, dealing with the following subjects: the structure and functions of organisms and the cell theory; the evolution of sex; variation and heredity; the theory and evidence of organic evolution, with particular insistence on adaptations; and, finally, the factors of organic evolution. What gives the book its particular merit, in addition to the indispensable qualities of lucidity and good judgment, is its concreteness. Prof. Dendy is always bringing the student into touch with concrete examples which illustrate the principles discussed and enable the reader to get a firmer grip.

There is throughout the book a scientific good humour. Thus when the author is discussing such a thorny question as the transmissibility of individually acquired somatic modifications, he is temperate in his language and judicial in his survey. He does not dogmatise and he does not suggest that the only tenable position is Lamarckian; and yet he is not in the least wobbly, as this quotation may show.

"On the whole, then, the available evidence seems to indicate that suddenly and exceptionally acquired characters, such as mutilations, are occasionally but only rarely inherited to such an extent as to be recognisable, while, on the other hand, characters which are due to the continued action of some external stimulus, extending perhaps over many generations, in the long run become so firmly impressed upon the organism that they affect the germ cells as well as the somatic cells and thus become truly blastogenic."

We happen to think that this is a misinterpretation of the evidence, but our point is that Prof. Dendy puts the problem before the student in an eminently fair-minded fashion.

The author wishes good speed to the investigators of the chemical and physical processes that go on in the living body, but he denies that the formulæ of chemistry and physics can be made to cover all the phenomena of life.

"We may, perhaps, believe that, as living matter became more and more complex in its structure, it entered progressively into new energy relations with its environment, which became more and more unlike those exhibited by inanimate matter, until at length they passed in some respects altogether beyond the reach of chemical and physical explanations."

This appears to us to be, on the whole, the scientific position at present, though the wording is a little suggestive of the idea that mind is a resultant of complexifying proteins and energy-relations, which is absurd, as Euclid used to say when he was tired. Moreover, it is open to question whether there is any "inanimate matter" anywhere. But what we wish to say is this, that if we shared Prof. Dendy's non-mechanistic views, as we do but more also, then we should not entitle a chapter "the mechanism of evolution." The point is that evolution transcends mechanism, and, if that is so, it is a pity to say mechanism when you only mean *modus operandi*. For there can be no doubt that if one says "mechanism" often enough in reference to vital processes, people will end in believing us, and we shall believe it ourselves!

We have referred only to a crumpled rose-leaf, for we really think that the book is as good as any book has a right to be. It is singularly attractive in every way—beautifully printed, with many interesting illustrations of great interest; and it is a personal deliverance. Most alteration, naturally, has been made in the part dealing with heredity. There is a valuable glossary, but we think it was a psychological mistake to put it in the forefront of the book. What a thorny hedge to these fair pastures!

Natural History of Pheasants.

A Monograph of the Pheasants. By William Beebe. In 4 volumes. Vol. 4. Pp. xv+242+23 coloured plates+27 photogravure plates+6 maps. (London: H. F. and G. Witherby, 1922.) 12*l*. 10*s*. net.

THE fourth and final volume of this great Monograph[1] treats of the golden pheasants (Chrysolophus), the bronze-tailed peacock pheasants (Chalurus), the peacock pheasants (Polyplectron), the ocellated pheasants (Rheinardius), the Argus pheasants (Argusianus), and the peafowl (Pavo).

These groups comprise forms of surpassing beauty of plumage and remarkable habits. The life-histories of a number of the species treated of were previously unknown, since no ornithologist had ever penetrated the remote fastnesses in which their lives are spent, while in the case of others much remained to be learned. Mr. Beebe's researches have lifted the veil which has hitherto masked the ways of many.

To the illustration of the seventeen species and subspecies here described, twenty-two coloured plates

[1] Previous notices relating to this Monograph appeared in NATURE, vol. 102, p. 302; vol. 107, p. 235; and vol. 110, p. 105.

are devoted; twenty-seven exquisite photogravure plates depict their haunts, nesting sites, courtship and dancing places; while a series of maps illustrate the geographical distribution of all the forms.

Regarding the two species of Thaumalea, the golden and Amhersts' pheasants, though both have long been familiar in captivity or in a semi-domesticated state, yet little or nothing was known of them in their native haunts. This is well illustrated by the case of the former bird. Although this beautiful species has been kept in captivity for centuries (even prior to 1747 in England) yet in a wild state probably no other pheasant was so absolutely unknown to naturalists. Mr. Beebe, however, succeeded in penetrating the bird's exceedingly remote retreats and gives a graphic account of its home-life in the deep rugged mountain forests of Central China. Here he witnessed its wonderful courtship, in which the gorgeous ruff of the male plays an important part, but all his endeavours, however, to find its nest were unavailing, and it still remains to be discovered. The same great difficulties were experienced in the search for the Amhersts' pheasant. For many days the bird remained but a phantom, until at last a glimpse of "its royal self" was presented in its remarkably fine home in the forests on the frontier of Yunnan and Burma, where it haunted the steep sides of lofty valleys traversed by rushing torrents. Here the author saw the cocks in all their glory of ruff and body-plumage, and beautiful beyond description. Apart from the pleasure of recording their actions, Mr. Beebe was not able to add much to the little already known, and failed to find a nest.

From discussing the typical pheasants the author proceeds to treat of those of the Argus group (Argusianinæ), commencing with the bronze-tailed peacock pheasant (Chalurus). This genus includes two species which are confined to the Malay States and Sumatra respectively. Both are rare in their native haunts and in collections, and have never been kept in captivity. Practically nothing was known of their life-histories prior to the author's investigations. The Malayan species (*C. inopinatus*)—"a true bird of the wildness"—inhabits the dense jungles of the central mountains of the Peninsula. Hitherto the knowledge of this species has been derived from skins, and many days passed after Mr. Beebe reached its haunts, which ranged from humid dark ravines to summit ridges where warmth and brilliance prevailed, ere he was able to catch even a glimpse of the bird. Eventually he came across a party from which he secured a specimen, and was shown a nesting site on the side of a rocky defile. The Sumatra species (*C. chalurus*) is an inhabitant of the interior of that great island, where no white man has seen it alive.

The peacock pheasants (Polyplectron) are ornamented with many gorgeous metallic eye-spots, which are most developed in the male and are displayed by him during courtship. Mr. Beebe found the grey-backed species (*P. bicalcaratum bicalcaratum*) occurring singly or in small families among the mountains of Burma and Western China, where they are shielded by terrible growths of thorn cane. They seldom fly, but skulk through the jungle in the day-time and roost on trees at night. Once the haunts were discovered they were found to be not very uncommon, and their courtship, one of the most remarkable among birds, was seen to commence with a lateral display, although the climax was reached in a wonderful frontal performance in which every ornament of the male's plumage was brought to bear to influence the little female. The Malay species (*P. malaccensis*) is a native of lowland jungle where it is well guarded by a myriad tropical terrors which rise at every foot to dispute advance into its domain. It proved to be the most difficult of the Malay pheasants to locate. Day after day the search had to be given up, and it was only when Mr. Beebe resorted to tracking by himself alone that success came, and even then he had to fight his way and suffer much for even a brief peep of these splendid birds. At last, however, in a land of dreadful silence, leeches, sand-flies and mosquitoes, he found the objects of his search in fair numbers. The Bornean species (*P. schleiermacheri*) is a native of the hilly jungle near the centre of the island. Of this species the author was only able to obtain a handful of feathers from a bird trapped by a Dyak, nor could he learn anything trustworthy about this pheasant from the natives, who are well versed in all the other species. Hence he concludes that it must be exclusively uncommon. Of the three other species of this genus, *P. katsumatæ*, *P. napoleonis*, and *P. bicalcaratum germaini*, he was unable to visit the haunts in the Islands of Hainan and Palawan and in Cochin China and Siam, but he gives accounts of their histories so far as they are known.

The ocellated pheasants (Rheinardius) are large birds as strange in appearance as they are rare and mysterious in life. Their general characters unite them closely with the Argus pheasants, but they are much less specialised. Like them they have the remarkable habit of clearing small tracts in forests as arenas for their displays. Two forms are known. The Annam species (*R. ocellatus*), a magnificent bird, has a singular history, for its identity was founded on several feathers, from an unknown source, discovered in the Paris Museum prior to 1856; but it remained undescribed, and it was not until 1882 that a specimen procured by Commander Rheinart set

all doubt at rest as to its distinctness. Very few examples have been obtained from its haunts in the dense mountain forests which separate the Laos country from Annam—a region which is inhabited by semi-savage tribes. The Malay species (*R. nigrescens*) is also very rare, and only a few specimens were procured among the central mountains of the Peninsula. Mr. Beebe tells us that it is the most mysterious of all the birds of the Argus group. He lived in their neighbourhood, heard their calls, found a dancing arena of an individual that had met with disaster, and yet, after weeks of search, he never caught a glimpse of the bird itself.

The Argus pheasants (Argusianus), of which three species are known, Mr. Beebe regards as being in many ways the most extremely ornamented and specialised members of the pheasant family. The adult males measure six and a half feet in length; two-thirds of this is taken up by the central tail-feathers, while "the ocelli on the secondaries are marvels of design and shading, resembling marble-like spheres revolving in separate sockets, and all with bright lights as exquisite and effective as if carefully planned for some exact and delicate purpose." The evolution of these "eyes" is illustrated in one of the coloured plates. The males make, and keep clear, large dancing areas in which they call the females and where they show off their marvellous frontal displays. Regarding the Malay species (*A. argus*) and the Bornean bird (*A. gnayi*), the author tells us that few white men have shot or seen them in their wild homes, owing to the fact that "no deliberate attempt has been made to circumvent the birds, or to adapt one's approach to the peculiarities of life habits." Hence he was very anxious to make as thorough a study as possible of these marvellous creatures. At first he was pessimistic, being told that he would not be able to get further than hearing the birds. Many of their habits are affected by their curious practice of creating special places—a cleared arena about three yards in diameter—in the forest jungle, where the male displays before the female. Mr. Beebe found that it was here alone that he could observe the birds, and, having made good use of this discovery, he has been able to give elaborate descriptions of what he observed. The third species, the double-spotted Argus pheasant (*A. bipunctatus*), is only known from a portion of a feather, without a history, found in the British Museum in 1871. This differs so decidedly from any corresponding feather in the known species, that the author has little doubt that it represents a distinct form.

For the two species of peafowl, Mr. Beebe has established a sub-family (Pavoninæ) "on account of the character of the tail moult, which typically is from the central pair outward." They also "form a distinctly isolated group, and we have no idea of their line of ancestry. The femoro-caudal muscle, for example, is absent in Pavo and in Meleagris [the Turkeys] while present in all other gallinaceous birds; the syrinx in Pavo is simpler than in any others of its family." Of the two species, the well-known Indian bird (*Pavo cristatus*), from which the domestic bird is descended, is a native of India, Assam, and Ceylon. Its habits are well described by the author from personal observation. Semi-domesticated peafowl occur in many parts of India and are considered sacred birds; while the black-winged form is a very remarkable sport or mutation occurring sporadically among domestic Indian birds, sometimes one or two appearing in a brood. Albino birds are never found in a wild state. The second species, the green peafowl (*P. muticus*), is a native of Chittagong, Burma, Siam, Cochin China, Malay Peninsula, and Java. The habits of the two species are almost identical, where Indian birds only are considered; but even where the green bird is most abundant, it occurs in small isolated groups, which are extremely sedentary.

Mr. Beebe is to be heartily congratulated on the completion of his great work. Many excellent Monographs devoted to various groups of birds have appeared, including princely volumes on the pheasants, but no treatise on any group has ever been so enriched by the researches of its author as this. Yet, Mr. Beebe, great traveller and naturalist as he is, only achieved success with many species through his unfailing enthusiasm and a remarkable display of indomitable determination. Indeed he failed only where success appears to have been humanly impossible.

W. E. C.

Vitamins.

Vital Factors of Foods: Vitamins and Nutrition. By C. Ellis and Prof. Annie L. Macleod. Pp. xvi + 391. (London: Chapman and Hall, Ltd., 1923.) 25*s.* net.

If there still remain people sceptical of the existence of what have been called "vitamins," this book should go far to convince them that there are certain elusive substances, present in food only in the most minute quantity, but nevertheless necessary to enable growth to take place and to maintain normal health. The reviewer is unaware of the publication of any other work on this subject of so comprehensive and impartial a nature as the present one. In a branch of knowledge on which so much research is still being carried on, it is not to be expected that the very latest discoveries should find their way to a text-book, but that of Ellis and Macleod appears to have

omitted little or nothing up to the date of its production. It will be found very useful.

Like most new and far-reaching discoveries, that of vitamins has not escaped the danger of being regarded as displacing or reducing to little importance previous work on such matters as the energy value of food. While it is perfectly true that, in the absence of vitamins, no amount of food, however great, suffices for health, it is nevertheless equally true that no amount of vitamins can compensate for a lack of energy value. In actual practice, however, there is, under certain conditions in which fresh vegetable food is absent from the diet, more risk of damage to health from this factor than from absence of total quantity. Such, for example, is the position of those populations which live mainly on rice, or in circumstances in which preserved or canned food is the chief article consumed.

The reviewer is glad to note that the authors have adopted Drummond's suggestion of dropping the final *e* of the original name "vitamine" and appending a capital letter to express the particular kind of vitamin referred to. This practice is rapidly being generally adopted, since it is, on the whole, more satisfactory than any other that has been advocated. The origin of the name will soon be forgotten and it will become just a name, like "enzyme," which does not suggest yeast whenever it is used. In connexion with the title of the present book, it may be noted that there are other factors of food equally as "vital" as vitamins. The term "accessory factor," sometimes used, is apt to suggest, on the other hand, that these factors are only of subsidiary importance.

A brief account of the elementary principles of nutrition precedes the main subject. This appears to contain all that is needed for the purpose. We may ask, perhaps, if water, salts, and vitamins are to be added to the traditional fats, carbohydrates, and proteins as necessary constituents of a diet, why omit oxygen? The first chapter is devoted to a general account of the nature of vitamins, with a history of their discovery. It is pointed out that we do not know how they act. In many ways they behave like catalysts; in other ways, they seem more related to the chemical messengers or hormones. McCollum directs attention to the fact that they do not behave as hormones in the sense of being produced in one organ for the purpose of bringing about reactions in other places. They are not formed by the animal organism at all, so far as we know.

A useful account of experimental methods is given in the second chapter. It is to be feared that inattention to freedom from traces of vitamins in the control diet has been the source of erroneous statements. As to their chemical nature, we have still practically everything to learn. Like enzymes and hormones, they are so extremely powerful that we can remove more and more unessential impurities from them, without affecting their activity. Thus we finally arrive at a trace of a substance which has very few chemical properties of any kind. Some method by which these substances can be readily separated from large quantities of the materials containing them has yet to be worked out. Possibly it may be found in an application of the adsorption method used with success by Willstätter in the case of enzymes.

The making of concentrated preparations is described, but it is to be regretted that the extravagant cost of commercial products in relation to their actual content in vitamins is not more insisted upon. As Drummond has well pointed out, eggs and oranges are equally useful at less than a fiftieth of the cost. If a reasonably varied diet with fresh fruit and vegetables be taken, there is no need to worry about vitamins. It is curious that so many people fail to realise that vitamins are not drugs, to be taken under medical direction, but natural constituents of food. It does not matter how much of them be taken, provided that it is enough.

Detailed discussion is given of the various disorders associated with deficiency of vitamins. It is here that the question as to whether there are more than the three (A, B, and C) vitamins comes into prominence. Three chapters are devoted to practical problems of appropriate diets for infants and adults, and a final chapter on the interesting question of the vitamin requirements of fungi, moulds, and bacteria is added. An appendix gives tables of the distribution of the vitamins in various articles of diet. It is a remarkable fact that although some animal products are rich in certain vitamins, the ultimate source of these appears to be in all cases the vegetable kingdom.

The book may be highly recommended. The work of so many different investigators is given that the reader is at times rather bewildered, and a summary of the established data, given at the end of each chapter, would be a welcome addition. There is, however, an excellent index. W. M. Bayliss.

The Atom of To-day.

The Structure of the Atom. By Prof. E. N. da C. Andrade. Pp. xv+314. (London: G. Bell and Sons, Ltd., 1923.) 16*s*. net.

To give a comprehensive critical survey of the prevailing theories of atomic structure and to indicate their triumphs and inadequacies in a volume of reasonable size is the professed object of the book under

review. This is a bold design. It is all the greater pleasure therefore to record that the book is an almost unqualified success. It is, moreover, heartily welcome, for it provides just that critical introduction to modern atomic speculations which should be in the hands of every student, and can be read with profit by most researchers. Such a book has until now not been available in English, and the want is scarcely filled by the recent translation of Sommerfeld's classic work, which is rather too long and elaborate and somewhat too one-sided (spectroscopic) to be entirely suitable in this connexion.

To come to details. The book is divided into two parts dealing with the existence and properties of the nucleus and with the extra-nuclear structure respectively. In Part I. after a short historical introduction, the first evidence for the exceedingly open structure of the atom is presented in detail, as derived from the passage of swift corpuscles through matter. An important feature is the account of the work of Lenard on the absorption of swift cathode rays, now too often overlooked, which started atomic speculation on its present path. There follows an excellent account of the work of Rutherford in establishing the nuclear structure, with its extensions by his school, and then the radioactive evidence, including the recent work of Ellis on the photoelectric effect and the interesting speculations of Meitner. There is next a discussion of the modern work on very close collisions between α-particles and light nuclei—artificial disintegrations by Rutherford, and the deviations from the law of inverse squares. A chapter on positive rays, with Aston's law of integral atomic masses, concludes the nuclear evidence. In this chapter there is one of the few questionable omissions. In a paragraph on the separation of isotopes, Harkins's work on hydrogen chloride is alluded to, but there is no mention of the very elegant work of Brönstead and Hevesy on mercury.

Part I. then concludes with a critical account of such theory of the nucleus as is yet possible, and two short but necessary digressions, one on X-rays from the classical point of view, and the other on the general empirical laws of optical spectra. Both are good, but exception can be taken to smaller points in the optical chapter. To emphasise the fact that the majority of known atomic spectra have not yet been ordered into series is to overlook the fact that the time is still short during which there has been a real theoretical incentive so to order a difficult spectrum. But the yearly output of such spectra at least partially ordered in series is now considerable. Again, it is unfortunate that it has been stated that atoms in general emit *two* optical spectra, when we now have Al III and Si IV. But this, no doubt, like the statement, already partly untrue, that there is no detailed theoretical foundation for optical terms of the forms of Rydberg and Ritz, is evidence rather of the present rate of progress than of inadequacies in the book. The general theory of these term-forms was announced by Bohr at the recent meeting of the British Association.

Part II., on the extra-nuclear structure, starts with two long chapters on the dynamical model of atoms of one and more than one electron. Clear as they are, these are the least satisfactory chapters in the book; we return to their consideration later on. They are followed by a concise account of Bohr's general theory of atomic structure, which could perhaps be bettered in minor points. The discussion of firmness of binding compared to orbits of the same quantum number in hydrogen could be made clearer by an explicit definition and use of "the effective quantum number" of the external Keplerian loop of the orbit and its relation to the actual total quantum number. Again, no clear distinction is made between the true relativity effect on a Keplerian orbit and the similar effect due to deviations in the law of force from the inverse square, such as occur in practice from the variable screening. Finally it is stated in error that the fifth and sixth electrons are bound in 2_1 and the thirteenth and fourteenth in 3_1 orbits—a statement contradicted by the relevant table on page 224. The error repeats an early statement by Bohr, which he has superseded by this table.

Following this there is an excellent sympathetic account of static models of the atom and their value in organising the facts of chemistry. This chapter makes it clear in an interesting way that though all attempts to make static models with any natural physical reality are a waste of time, such models, like the elastic spheres of the kinetic theory, have a large legitimate "place in the sun." The book concludes with what should prove a very useful survey of the present chaotic state of magnetic theory.

To return to the chapters on the dynamical atom. The reviewer would make the general criticism that they present the subject from a point of view which, without prejudice, may be called too "Sommerfeldian." Without in any way belittling Sommerfeld's classical contributions, it is the correspondence principle and the fundamental frequencies of the atomic system, Bohr's method of attack, and not the Wilson-Sommerfeld quantum conditions, which ought to be made fundamental, above all in a book for physicists. "Ought" is the word, for reasons which the author of this book has himself formulated as clearly as possible, for this is the method which seems to work best, and to be in closest touch with physical reality. His prefatory quotation of Kelvin should be re-quoted—"Nothing can be more fatal to progress than a too confident reliance on mathe-

matical symbols; for the student is only too apt to take the easier course, and consider the formula and not the fact as the physical reality." In effect this makes the section on elliptic orbits sad reading; we are also given Sommerfeld's admittedly unsatisfactory attempt to give a theoretical basis for Ritz's term-form. It is much to be desired that we might have had instead Bohr's elegant proof of the Rydberg form for central orbits (now superseded, as mentioned above), which is both physically and mathematically unexceptionable. It is possible that this was not available to the author, though it has been current for some time.

It is only just and right, however, that this review should close as it began on a note of praise, for the merits of the book are many and its defects few. No one can have anything but praise for the system and selection of references which leave nothing to be desired, and for the exquisite photographs by Blackett, Aston, Paschen, Siegbahn, and de Broglie reproduced in the four plates. The book should go through many editions—the more the better.

R. H. Fowler.

The Physical Aspect of Physiology.

(1) *Interfacial Forces and Phenomena in Physiology: Being the Herter Lectures in New York in March, 1922.* By Sir William M. Bayliss. Pp. ix + 196. (London: Methuen and Co., Ltd., 1923.) 7*s.* 6*d.* net.

(2) *The Vaso-Motor System.* By Sir William M. Bayliss. (Monographs on Physiology.) Pp. v + 163. (London: Longmans, Green and Co., 1923.) 7*s.* 6*d.* net.

(3) *The Electrical Action of the Human Heart.* By Dr. Augustus D. Waller. Edited by A. M. Waller. Pp. ix + 103. (London: University of London Press, Ltd., 1922.) 7*s.* 6*d.* net.

HOWEVER distinguished a man of science may be, we still expect the books he writes to increase his reputation. These two books by Sir William Bayliss will scarcely do this. It is not that they are bad books, but that they are not good enough for so distinguished an author.

(1) The volume on "Interfacial Forces and Phenomena in Physiology" is lucid and readable, and will certainly stimulate to further thought many who are interested in the problems lying on the borderland between the physical and the biological sciences; but here its virtues end. In the first chapter we are introduced to the electron theory of the atom and the latest work on crystal structure; but the promise of this chapter is not maintained. The treatment of the subject is almost exactly the same as that in the first edition of the author's "Principles of General Physiology." Though the advances of the intervening seven years are mentioned their bearing is not always recognised. For example, Sir William Bayliss persists in calling protein solutions "emulsoid," while confessing that emulsions never behave like protein solutions, and he makes no use of the insight into the constitution of colloidal solutions that the work of McBain gives us. It is probably the hypnotic effect of the word "emulsoid" that makes the author assume that a protein solution must inevitably behave as a heterogeneous system.

The classical theories of surface tension and adsorption are all based on statistical mechanics, and it is just when we come to the mechanism of the living cell that statistical theory fails us. These theories have been available to physiologists for many years and have been of scarcely any use because no precise deductions can be made from them in connexion with physiological problems. The new treatment of surface phenomena that we owe to Langmuir and to Adam holds immense possibilities for the physiologist, yet Sir William Bayliss dismisses Langmuir almost summarily. There are cases where statistical theory is of use to physiologists, notably in the treatment of processes that go on in a relatively simple medium, such as blood. The particular theory that has proved of most use here is the Law of Mass Action, but this law we are told we ought not to use. Sir William Bayliss adopts the attitude of one who reproves a friend for removing a nut with hammer and cold chisel, while he admits that the only spanner available does not fit.

(2) The book on "The Vaso-Motor System" is more purely technical. It contains a useful summary of the work done on the control of the blood flow through arteries and capillaries. Much of the evidence at present available is confused and conflicting. As one of the most successful investigators in this branch of physiology, we might reasonably have expected Sir William Bayliss to sum up the evidence judicially, and to give us the benefit of his conclusions on doubtful points. This he does not do. He merely states all the results obtained by all the workers, and leaves the reader to pick his way among them as best he can.

(3) The late Prof. Waller's book on "The Electrical Action of the Human Heart" consists of a series of four lectures delivered by the author in 1913. The first two lectures contained a résumé of certain facts and theories based on the author's work with the capillary electrometer, and a comparison of these early results with those obtained by means of the string galvanometer of Einthoven. The remaining

two lectures are devoted to a discussion concerning the significance of certain features of the electrocardiogram.

From a historical point of view, this little book is of considerable interest; but, in a subject so young as electrocardiography, a period of ten years is sufficient to bring about considerable modification in views previously current, and the omission of references to the more recent work cannot fail to detract from the value of hypotheses based on the earlier experiments. One cannot help feeling that the views expressed are those of an advocate rather than a judge. In such small and unimportant details as the nomenclature of the different deflexions of the electrocardiogram, it is somewhat surprising that a pioneer worker in this branch of physiology should be so reluctant to adopt a phraseology which is now almost universally employed.

Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1922.) 30*s*. net.

(4) *Cours de chimie organique*. Par Prof. F. Swarts. Troisième édition, revue et augmentée. Pp. iii + 674. (Bruxelles: M. Lamertin; Paris: J. Hermann, 1921.) 50 francs.

(1) METHODS of preparation in organic chemistry, like all other branches of the science, tend to become out-of-date, and probably every teacher has his own list, culled from recent literature, which he gives to those students who have to bridge a gap between "preparations" and "research." Indeed, if properly chosen, supplementary preparations of the kind mentioned lend themselves admirably for the purposes of initial instruction in the methods of research, when, as sometimes happens, the research on which the advanced student is started does not involve the preparation of large quantities of initial material.

The book under review contains a number of preparations of this kind which the author has collected after many years of experience of teaching and research, and these he now offers to his fellow-teachers with an apology in his prefatory note for the fact that many of the details have been taken from his own work and that of Dr. Walter A. Jacobs, of the Rockefeller Institute. Organic chemists will, however, know that it is the first-hand information that counts, and that the author writes of a subject with which he is fully competent to deal.

The book is well printed and easy to read. The printer has evidently experienced difficulty in setting up some of the more complex formulæ, and the result is, in some cases, apt to make one dizzy, but, even thus, it is better than the easier and cheaper method of attempting to represent such formulæ in a straight line. Dr. Heidelberger has produced a useful little book for those teachers of organic chemistry who may wish to give their advanced students some more difficult preparations than those usually to be found in the ordinary laboratory manuals.

(2) This is the second volume of the series and is well up to the high standard set by the first. Twenty-five preparations are described, and all of them deal with compounds likely to be required in an organic chemical research laboratory. Each substance is treated under three headings, namely, (1) procedure, (2) notes, and (3) other methods of preparation; the method of procedure being given in sufficient detail to enable an ordinary advanced student to follow it with ease. The notes are in every case well written and give valuable and essential advice which will be of the greatest assistance to those who have to carry out the preparations. Brief but cogent criticisms are given of other methods of preparation in the sections devoted to this head, and the reasons why such methods have proved unsatisfactory in practice are clearly stated.

In every case the preparation has been carried out by one of the associated editors and checked by another, and as all four of them are organic chemists of high standing, there is no room for error. If it were possible to make this admirable compilation still more admirable, it might be done by a freer use of graphic formulæ at the heading of the chapters—they take more room, but are well worth it—and by pandering to English laziness by giving where possible the volume of solutions as well as the weight. For example, on p. 75, the expression "400 g. of 28 per cent. ammonium

hydroxide" means a calculation and therefore extra work.

(3) Looked at from the point of view of a research chemist of some thirty years' standing, the first feeling produced on reading Prof. Mulliken's volume is one of doubt as to whether the immense labour and skill expended in its compilation were really worth while; the second is a sense of disappointment that, by the exclusion of all references, an opportunity has been lost of making the treatise of real value to research workers; for it can scarcely be doubted that the work is intended for the research chemist, because who else would be interested in the vast number of compounds tabulated?

The author's "method" may, and probably does, do all that he claims, but it is scarcely conceivable that any organic chemist would use it, even if he had sufficient time at his disposal to enable him to do so. The vast majority of organic chemists, when they isolate a new compound, subject it first to an elementary analysis and then determine its empirical formula by the usual methods. They then look up the formula in Richter or in one of the many annual or decennial indexes based on empirical formulæ, as indeed they all are, and then refer to the literature. Even then identification can never be regarded as certain until direct comparison has been made. Physical properties and chemical reactions are interesting, but often misleading, and the lack of any reference to the literature prevents the chemist from doing the one thing he ought to do, that is, to prepare some of the material and compare it with that which he has obtained. In the event of the substance being too difficult or too expensive to prepare, there is another, though less satisfactory, method for establishing identity, and that is by preparing some crystalline derivative and comparing this with the same derivative prepared from the standard. But here again the author does not help, because he mentions no derivatives. If he had given references and had described one or two typical derivatives, the book would doubtless have been larger, but it would have been infinitely more useful.

(4) The book before us is the third edition of a work which evidently finds a considerable sale on the Continent. It is, as the author says, "un cours" and not "un traité," and does not, therefore, pretend to cover the whole field of the special subject with which it deals. Nevertheless the book contains 674 pages, and it should be possible to deal with most of the more important aspects of the science in this space. On the whole, the author has succeeded in compiling a readable book, and one which should be of great use to the student, provided he has facilities for acquiring help in the initial stages to fill the gaps which the author has left. It is, for example, unlikely that the student would obtain a working knowledge of stereoisomerism or of tautomerism from the rather meagre descriptions given in this book. Indeed the basic theoretical parts are too short and too difficult to follow. Otherwise the book is a valuable one and is well printed and set up. J. F. T.

The Composition and Examination of Volatile Oils.

The Volatile Oils. By E. Gildemeister and Fr. Hoffmann. Second edition, by E. Gildemeister. Written under the auspices of the firm of Schimmel and Co., Miltitz, near Leipzig. Authorised translation by Edward Kremers. Third volume. Pp. xx+777. (London: Longmans, Green and Co., 1922.) 32*s*. net.

WITH the volume before us the English translation of the second edition of Gildemeister and Hoffmann's "Volatile Oils" is now completed. The publication of the book has unfortunately been very materially delayed by the War, so that a period of no less than nine years has elapsed since the appearance of the first volume in 1913, and there are but few references to the results of investigations published since 1915. In the second volume the oils derived from plants belonging to a number of families were dealt with in detail; in the present work those obtained from the Rutaceæ (including, therefore, lemon, orange, and other Citrus oils), Burseraceæ (myrrh and elemi), Dipterocarpeæ (Borneo camphor oil), Myrtaceæ (myrtle, pimento, bay, clove, eucalyptus, cajuput), Umbelliferæ (caraway, dill, anise, celery, ajowan, asafetida), Ericaceæ (wintergreen), Labiatæ (lavender, sage, thyme, mint), Compositæ (chamomile, wormwood), and many other families, are considered.

The thoroughness with which the task has been attacked may be well exemplified by the monograph on lemon oil. Tables of statistics are followed by a map showing the districts of production of lemon, orange, and bergamot oils in Sicily and Calabria. The various methods of extracting the oil are then carefully described and the descriptions illustrated by a number of photographic reproductions. The properties and constituents of the oil are next exhaustively dealt with. Details of the chemical examination of the oil occupy 24 pages. No fewer than eleven methods of determining the citral present are described, and, which is most important, the objections to their use, and the results of the methods when tested in Messrs. Schimmel's laboratory, are appended.

Here and there in the work statements may be met with that are now no longer correct; thus on p. 492

carvacrol is said to be the only phenol present in Spanish oil of thyme, whereas Mastbaum has shown that the Spanish oils of *Thymus vulgaris*, *T. Zygis*, *T. hiemalis*, and *Corydothymus captatus* all contain notable proportions of thymol; in this case at least the discrepancy may be due to the length of time that has elapsed between the completion of the work and its publication. To clove oils 18 pages are devoted, and here also the description is accompanied by a map of the islands of Pemba and Zanzibar showing the distribution of the clove plantations. For the determination of the percentage of eugenol in the oil a 3 per cent. solution of sodium hydroxide is recommended, whereas in the "British Pharmacopœia" a 5 per cent. solution (of potassium hydroxide) is given.

Eucalyptus oils are very fully represented, no fewer than 141 being mentioned, the great majority of them, however, being of scientific rather than economic value. The commercial oil of *E. amygdalina* is now referred to *E. amygdalina*, Labill., var. *Australiana*, Baker and Smith.

The task of translation, always a rather tedious one, has been admirably accomplished by Dr. E. Kremers, of Madison, Wis. The work is couched in excellent English, reads very easily, and shows only occasionally a somewhat literal rendering of the German original. Both paper and type are good, and clerical errors are seldom to be found.

Viewing the work as a whole, one cannot but be surprised at the mass of information which has been collected by the author, sifted in the laboratories of Messrs. Schimmel, and is now offered to the scientific world. Notwithstanding the disadvantages under which the book has been compiled, translated, and issued, it must be regarded as one of the most complete in existence on the subject. It will doubtless prove a mine of information for all workers on volatile oils, and it is difficult to see how any scientific library can be complete without it.

Low Temperature Carbonisation of Coal.

Low Temperature Carbonisation of Bituminous Coal. By A. McCulloch and N. Simpkin. Pp. xii + 248. (London: H. F. and G. Witherby, 1923.) 18*s*. net.

THE low temperature carbonisation of bituminous coal is a process which has received much attention from writers, speakers, and experimenters, and Messrs. McCulloch and Simpkin have made a useful summary of the work that has been carried out. The preface insists quite rightly upon the importance of the subject in connexion with atmospheric pollution by smoke. If commercial success can be attained "Not only will it be possible to ensure a smokeless atmosphere, but, at the same time, a considerable conservation of our coal resources will result, and the country will be provided with a home supply of fuel oil."

The constitution of coal, the history of attempts dating from Parker's "Coalite" process to solve the problems of low temperature carbonisation, the difficulties arising from the expansion of coal on heating and its low thermal conductivity, the processes connected with the names of McLaurin, Del Monte, Fischer and Gluud, Illingworth and others, the nature of coal tar and of low temperature tar in particular, are discussed in turn in the seven chapters of the work. The printing is clear, and forty-three illustrations are given, most of them useful line drawings of plant, but some of Sir George Beilby's microphotographs of coke are included.

It is very difficult to write a book of this kind judicially and critically as regards large-scale operations, unless from a first-hand experience, to which the authors do not seem to make any claim either in the preface or the text. The account of each process in existing circumstances remains to a great extent a repetition of the claims made for it, although an exception must, of course, be made of those experiments which have been made and fully described by the Fuel Research Board.

The more theoretical portions of the book make mention of many researches, apparently more than have been digested. Thus, perhaps, the most striking result obtained by Messrs. Greenwood and Hodsman in their work on "The Factors Influencing the Yield of Ammonia during Carbonisation" was that oxygen did not decompose the ammonia, but was used up in the preferential combustion of other substances. The work is referred to by the authors on p. 33, but on p. 34 they say that "the presence of oxygen is detrimental to the formation of high ammonia yields since it decomposes the ammonia produced."

On the whole, however, the book stands as a good and readable account, brought well up-to-date, of a very important side of modern experimental developments in the utilisation of coal. J. W. C.

Complex Space.

Prolegomena to Analytical Geometry in Anisotropic Euclidean Space of Three Dimensions. By Prof. E. H. Neville. Pp. xxii + 368. (Cambridge: At the University Press, 1922.) 30*s*. net.

WERE a Greek from the Academy of Plato to visit England, it would surely please him to find a title he could read without using a dictionary. Should

he persist in acquainting himself with the first chapters, he would be delighted with the precision of language and thought and with the homeliness of the contents; indeed, it may be said that the number of readers of this beautifully executed work will be a fair measure of the Greek spirit among our geometers of the present day. To barbarians it will seem to cut right across the course of modern geometry with an independence which shows itself in nomenclature and notation, in absence of references, and most of all in the limitations which the author has placed upon himself in the selection of his material. This is partly accounted for by the fact that Prof. Neville is avowedly a disciple of Mr. Russell, whose well-known aphorisms are scattered over the book, and it is scarcely to be expected that a subject written in the form which modern logic demands should develop itself along lines which appear fundamental in discovery.

The earlier part of the book is an introduction to vector analysis followed by an excellent discussion of Cartesian axes and vector frames. Perhaps it should be mentioned that "anisotropic" space does not imply any "medium" theory—Prof. Neville's words have no implications but are equivalents of the symbols of the Principia. Anisotropic space is flat space of three dimensions which does not touch the absolute in four dimensions. The second half of the book is devoted to the construction of algebraic space out of those properties of vectors and points which were suggested as significant in the earlier chapters. This is a most valuable contribution, and we confine our attention to it.

Geometers say that a circle is cut by a line of its plane at two points, real or imaginary. There are great advantages in doing so, but if asked for reasons they content themselves with explaining that this is a conventional way of talking and that imaginary "points" merely stand for certain pairs of imaginary numbers. How they stand for them is not clear. To find a logical basis one of two methods may be adopted. The first, that of von Staudt, consists of replacing the imaginary points by an equivalent real elliptic involution: any construction which has been algebraically thought out by the use of imaginaries at intermediate steps can be replaced by a more elaborate real construction which can be actually carried out by pencil on paper. This method has the beauty of being geometrically relevant.

The second plan, which is that adopted in this book, has the logical advantage of allowing the real points no special privilege. Algebraic complex space is built up from such fundamental relations as hold between vectors and vectors and between vectors and points in ordinary geometry; in other words, we remove the loose convention or postulate used by the "teacher in a hurry," and carefully devise a unique construct within which all the required operations can be carried out. This however has obvious geometrical disadvantages, as it involves an embarrassing array of relations in which we have no reason to be interested.

It may be doubted if there can be any true interpretation of a space in the modern sense which does not deal with the group of transformations for which it is the accepted field. The ordinary geometry, as introduced by Prof. Neville, involves lines, directions, distances, all accepted from experience; no such geometry can dispense with the idea of motion unless it has first laid down a series of postulates such as he dislikes. This geometry, which he repeatedly refers to as "kinematical," cannot be any more logical, and is far less vivid when all reference to motion is excluded. His original space is the field of such transformations, and as such is really trivial in the complex domain. "To use geometrical language," writes Russell, ". . . is only a convenient help to the imagination." Prof. Neville's geometry reminds us of the notorious Euclidean point when it has moved, for what help to the imagination can come from a discussion of lines perpendicular to themselves or the bizarre metrical geometry of the isotropic plane? Just as the logician objects to Staudt's method as a search for complex space within real space, we fear most geometers will not pleasantly accept the task of picking out projective properties from the mass of metrical relations which Prof. Neville's method imposes on them.

George Westinghouse.

A Life of George Westinghouse. By Dr. Henry G. Prout. (For a Committee of the American Society of Mechanical Engineers.) Pp. xiii + 375. (London: Benn Bros. Ltd., 1922.) 18*s.* net.

THE American Society of Mechanical Engineers has undertaken to issue volumes devoted to the lives of some of its great men; and the supervision of the work has been entrusted to a committee of the Society. The first book of the series was a special edition of the autobiography of John Fritz, honorary member and past president. The present volume is the second of the series.

In the almost complete absence of personal records, letters, notes, and other material from which a biography could be prepared, the committee has had to draw upon the memories and impressions of those men still living who were nearest to Westinghouse, and the editor's duty has been to co-ordinate their contributions. This method of preparing a biography has both its

advantages and disadvantages; for while it helps towards the forming of a reasonable perspective, the result is rarely of any great literary interest. Such an interest, although of secondary significance during the man's generation, is a considerable asset to the perpetuation of his memory.

The genius of George Westinghouse is expressed in patent specifications and in industrial processes and products. On account of the diversity of these activities the editor has considered that a chronological survey would be confusing, and the record of achievements is dealt with under the different subjects to which they apply; in this manner an admirable summary is presented of the work of Westinghouse and its value in the world of industry.

The two major achievements made by Westinghouse were the development of the air-brake, which greatly influenced railway transport, and the application of alternating currents in the production and distribution of power. In the former he acted primarily as an inventor, in the latter as an industrial organiser. Both activities resulted in the evolution of industrial concerns, vast in size and ramifying in many directions. At the present time some seventy of these concerns exist. In other fields, he developed the use of natural gas at Pittsburgh and took out thirty-eight patents in this connexion; he did important work both in steam engineering and railway signalling, and in forty-eight years he took out some four hundred patents.

Whether Westinghouse was greater as an inventor or as a manufacturer is debatable, but both his inventions and his industrial ventures would have suffered much without this unique combination of capacities.

The greater part of the book deals with a survey of technical and manufacturing achievements, but the two concluding chapters give a well-drawn portrait of Westinghouse—the man. The editor shows him to be a man possessing almost superhuman qualities linked with very human weaknesses, a man of impelling personality, an idealist whose feet were firmly planted on the ground, a genius in imagination and vision, with marvellous powers for concentration, persistence, audacity, and fortitude to carry the fruits of his genius to such conclusions that they enormously benefited mankind. Perhaps the greatest weakness that is evident from the editor's presentation is a too great self-reliance and an inflexibility of mind when once a decision had been made. A most outstanding characteristic was his capacity for leadership, and his relations with his men were inspired by a man-to-man comradeship and good feeling, an instinct which has become traditionally known in industry as "the Westinghouse Spirit," which in its essence embodies in the highest degree loyalty and enthusiasm.

Aristotle and Physical Science.

(1) *Aristotle: on Coming-to-Be and Passing-Away.* (De Generatione et Corruptione.) A Revised Text, with Introduction and Commentary by Harold H. Joachim. Pp. xl+303. (Oxford: Clarendon Press; London: Oxford University Press, 1922.) 32*s*. net.

(2) *The Works of Aristotle: Translated into English. Meteorologica.* By E. W. Webster. Pp. vi+140. (Oxford: Clarendon Press; London: Oxford University Press, 1923.) 7*s*. 6*d*. net.

(1) THE treatise "On Coming-to-Be and Passing-Away" is one of very great interest to the pure Aristotelian. The question discussed in it is this: the four most elementary substances known to us being earth, air, fire, and water, how do these change into one another and how do they form less simple substances such as flesh and bone? For example, what happens when water is boiled in a kettle? To such questions as this the Atomists had already given an approximately correct answer. The scientific man will naturally ask whether Aristotle made any real advance on his predecessors; if he did not, why should we trouble ourselves about his views on such problems? It must be regretfully admitted that he did not make any such advance.

Aristotle seems to have been a good deal impressed by the atomic solution, but refused to accept it, criticising it with some severity, as indeed he always does criticise with severity all his forerunners. But what better had he to offer? Matter, says he, is one substratum underlying all phenomena: so far perhaps we agree with him, since modern science more and more tends towards belief in one substratum, and the weak point of the old Atomists was that they preferred a multitude of different groups of absolutely primitive matter, as Dalton did. Again, this substratum assumes the forms of the four so-called elements (which are not, strictly speaking, "elements" for Aristotle). Now if this could be interpreted to mean that the substratum appears in the four forms of solid, liquid, gaseous, incandescent, it would be very good sense, but unluckily Aristotle never put it that way. No, they are somehow formed by combinations of the two pairs of contraries, hot and cold, dry and moist: when water is boiled, the cold-moist is transformed into the hot-moist; and the efficient cause of these combinations and transformations is the movement of the heavens, in particular of the sun. Certainly the scientific man will be tempted to wish with Bacon that Democritus had come down to us instead of Aristotle—at least so far as this question is concerned.

But the pure Aristotelian does not fret himself over such considerations. His one aim is to understand the

meaning of his master and to delight in the subtleties of that astonishing world of close-packed thought, microscopic and yet universal. He will, like Prof. Joachim, find this treatise "fascinating and masterly," and he will give thanks unstinted to him for his superb exposition of it. Only those who have wrestled with the prodigious difficulties of such a work for themselves can appreciate the learning and mastery shown by him on every page of his commentary. The text also is very greatly improved: it is something of a shock to learn how untrustworthy is that of Bekker which we have been in the habit of accepting without demur.

(2) This miscellaneous work discusses various phenomena of the heavens (such as clouds, comets, the rainbow), the nature of the sea, earthquakes, wind, thunder, many properties of "composite bodies" such as iron, wood, honey, and plenty of other things besides. The admirer of Aristotle's biological works will be sorely disappointed by it; here are none of the flashes of insight and the grand generalisations which astonish us in those works, but here are his vices to be seen in abundance, especially the almost total absence of experiment, and the failure to test his hypotheses, the need for doing which he might have learnt from Socrates. One soon becomes weary of reading one facile explanation after another, almost always on wrong lines: for example, the Milky Way is "a fringe attaching to the greatest circle and due to the matter secreted." At the same time, it is of some interest, as testifying to the universality of its author's outlook on the world; "the number of things that man spied into," said Goethe of Aristotle, "is beyond belief." Perhaps the most interesting observation is that "we have only met with two instances of a moon rainbow in more than fifty years," which shows how Aristotle kept his eyes open; how many of us have seen two of them? But it is not given to any one man to be supreme alike in biology and physics.

The translation is excellently done, and Webster's early death—he was killed in battle in 1917—is a sad loss to scholarship.

A Survey of Scientific Literature.

Statistical Bibliography in Relation to the Growth of Modern Civilization: Two Lectures delivered in the University of Cambridge in May 1922. By E. Wyndham Hulme. Pp. 44 + 5 Tables + 4 charts. (London: Grafton and Co., 1923.) 6*s*. net.

THIS book contains two out of the four lectures delivered by Mr. Wyndham Hulme as Sandars reader in bibliography at the University of Cambridge in May 1922, and forms a notable contribution to the science of bibliography. Mr. Hulme's thesis is the need of co-operative action in bibliography, and in these lectures he urges as an example of this need the importance of bibliographical data as an aid to the illustration and interpretation of changes in the progress of modern civilisation.

The growth of scientific literature as a measure of man's activity has not been generally recognised—though the records previous to the nineteenth century are as a rule much more full and trustworthy than the ordinary data of the statistician—and Mr. Hulme here shows by means of graphs and tables how bibliographical statistics may not only serve to confirm conclusions already reached from other sources, but may also aid us to define and explain more precisely important movements of our social and industrial history. He takes as an example the International Catalogue of Scientific Literature as being fairly representative of the world's scientific literary output, and has compiled statistics for the years 1901 to 1913 for each of the 17 sections into which that work is divided, and correlated these with statistics of patents for invention, trade, population, etc. The figures given from the International Catalogue admittedly cannot be taken as final, for they are not only themselves subject to many adjustments, but they are also confined to the literature of pure science, and any influence that may have been exerted by advances in technology is obscured. Moreover, each branch of science is treated as a whole, and the behaviour of the various subclasses within each branch and their interrelation cannot therefore be studied. Nevertheless, the figures show certain features which would probably not be greatly modified by a more detailed examination. There is, for example, an undoubted indication of the rhythmic progress of a science, which appears to proceed in alternate periods of growth and stagnation and rises to a period of maximum output which in some cases it may be possible to predict. The year 1910 seems to have been a peak year, for there is evidence of a general falling off in all sections of the Catalogue and in patents after that year, but unfortunately the confusion arising from the War has so vitiated all statistics for years later than 1913 that it is impossible to check the extent and the duration of this depression.

Another surprising feature to which Mr. Hulme directs attention is shown in the geographical distribution of the journals indexed in the Catalogue throughout the period 1901–13. The figure for Germany and Austria is only just less than those for France, Russia, the United States, and Great Britain combined, while these four countries follow in the order given, with Russia appreciably higher than the United States or Great Britain.

In connexion with the English patent statistics which

Mr. Hulme gives from 1561 to date, the introduction of the patent specification about 1730 is an important landmark which should not be overlooked. Its need arose out of the increasing specialisation in industry—itself a sure indication of the commencement of industrial growth—and its establishment as a permanent part of patent practice so long after the introduction of the patent system is a parallel to the long time-lag that existed up to the eighteenth century between actual practice and its corresponding literature. This time-lag and the early divorce of industry from literature are well shown by Mr. Hulme in two interesting "tabular surveys" of the literature of architecture and the textile industries which give the earliest printed monograph in the different subdivisions of these two subjects, and in themselves form valuable bibliographical charts.

It is, however, more with the method advocated than with the conclusions drawn by Mr. Hulme—important and interesting as these are—that we are here concerned, and it is to be hoped that both bibliographers and statisticians will realise the utility of this new apparatus which may not unworthily play its part in the elucidation of many problems.

Our Bookshelf.

Catalysis in Organic Chemistry. By Paul Sabatier. Translated by Prof. E. Emmet Reid. Pp. xxiv+406. (London: The Library Press, Ltd., 1923.) 25*s*. net.

PROF. SABATIER'S book, of which an American translation is now issued, has been written on a basis which is considerably broader than the brilliant researches with which the name of the author is universally associated, and is very far from being a mere résumé in book-form of those researches, valuable as that would be. It is also more than a mere text-book for the instruction of students, since, instead of giving merely a few illustrative examples of particular types of chemical change, the author has usually enumerated all the most important examples, with references to the original literature in which they are described. The result has been to produce a monograph of remarkable completeness, in which the references alone would cover many pages, since they are several thousands in number.

The translation has been well done, although English readers will be amused to see on p. 25 a sentence which ends in a hyphen as a result of a refusal to repeat the second half of a name, which has already been printed on the preceding line. The pagination of the book is also very confusing, since, in opposition to all English precedents, the outer corners are occupied by paragraph numbers, the page-numbers being relegated to the inner corners, until the index is reached, when they revert to the usual position, thus giving the impression that 969 and 350 are consecutive pages. A very full author-index and subject-index have been added by the translator, in which again a novel system has been adopted, since all the references are to paragraphs and not to pages.

The American translation contains a supplementary section of 12 pages by Prof. Bancroft on "Theories of Contact Catalysis," and a number of signed footnotes by American workers. A biography, covering two pages only, is of very real value in directing attention to the range of Prof. Sabatier's researches, since his earlier work in inorganic chemistry has been largely overshadowed by the brilliancy of his later work in organic chemistry. It is also of interest to read that in 1907 he declined an invitation to follow Moissan at the Sorbonne, preferring to retain the chair of chemistry at Toulouse, which he has now occupied for nearly forty years.

The Wheelwright's Shop. By George Sturt ("George Bourne"). Pp. xii+236+8 plates. (Cambridge: At the University Press, 1923.) 12*s*. 6*d*. net.

THE title of this book gives no indication of the enjoyable nature of its contents. The author transports us into rural England as it was before the hand craftsman had disappeared before the march of machinery, and lets us into the secret of how these men found their working lives to be worth living. The knowledge which comes to the man who has to get out his own timber by the use of hand tools, and the intimate acquaintance with its peculiarities so acquired, are possessed by few workmen to-day. The book is very human, and is diversified throughout by quaint touches which throw a flood of light on the development of village life in England. Such a book could not be written except by one who had lived among the things described, and was intimately acquainted with the people. The wheelwright's shop still exists in Farnham, although it has moved with the times; its first records date back to 1706, and it came into the possession of the author's grandfather in 1810 and remained in the family until 1920.

The reader will learn a great deal more than how waggons and carts used to be built. "In the slow transition from village or provincial industry to city or cosmopolitan industry, one sees a change comparable to the geologic changes that are still altering the face of the earth. Already, during the eighties and nineties of last century, work was growing less interesting to the workman, although far more sure in its results. Whereas heretofore the villager had been grappling adventurously and as a colonist pioneer with the materials of his own neighbourhood, other materials to supersede the old ones were now arriving from multitudinous wage-earners in touch with no neighbourhood at all, but in the pay of capitalists. So the face of the country was being changed bit by bit . . . village life was dying out; intelligent interest in the country-side was being lost. . . . Seen in detail the changes seemed so trumpery and in most cases such real improvements. That they were upsetting old forms of skill—producing a population of wage-slaves in place of a nation of self-supporting workmen—occurred to nobody." The book can be recommended thoroughly to all who wish to extend their knowledge of their fellow men and who are interested in modern welfare problems.

Physics in Industry. Lectures delivered before the Institute of Physics by Prof. A. Barr, Sir James Ewing, and C. C. Paterson. (Oxford Technical Publications.) Vol. 1. Pp. 59. (London: H. Frowde and Hodder and Stoughton, 1923.) 2*s.* 6*d.* net.

THE first of these three lectures directs attention to the great complexity of the problems with which the engineer has to deal; and to the fact that, in many problems of design it is practically impossible to proceed by the method of scientific experiment; "his own experience and his inheritance of the accumulated results of the labours of his predecessors" must largely guide the successful engineer. Sir James Ewing deals with the relation of the physicist to the developmental history of the heat engine, and states that "the impulses towards any new departure are, in general, given by men who are at home in that delightful country which may be described as the borderland of physics and engineering. I have roamed in it for many happy years, and have been privileged to know some of the great men who have dwelt on its hill-tops. I have enjoyed its morning mists and its changing landscapes." The third lecture gives the experiences and views of a research physicist, working with an important electrical company which manufactures most of the machines, apparatus, and accessories made use of in modern electrical practice. His views on the duties and methods of the research organisation of such a company are of the highest importance, and should receive very close consideration by all who are interested in industrial research.

(1) *Essentials of Modern Physics.* By C. E. Dull. Pp. xi+525. (London, Calcutta and Sydney: G. G. Harrap and Co., Ltd., 1923.) 5*s.*
(2) *The Elements of Applied Physics.* By Prof. A. W. Smith. Pp. xiv+483. (London: McGraw-Hill Publishing Co., Ltd., 1923.) 12*s.* 6*d.*
(3) *Practical Heat.* Edited by T. Croft. (Power Plant Series.) Pp. xiii+713. (New York and London: McGraw-Hill Book Co. Inc., 1923.) 25*s.*

IN our issue of December 9, 1922, p. 792, we directed attention to the first of a series of reports on the teaching of physics in the United States by a committee of the American Physical Society formed to investigate the subject and to make recommendations for the future. The three books under notice may be regarded as outcomes of that report, for their aim is to provide a sound knowledge of the fundamental principles of the subject and to show how those principles find their applications in the common experiences of everyday life. The first is for secondary school use and introduces each principle by a familiar fact depending on it, the second supplies the needs of a student in his first year at a University intending to become an engineer, while the third is a more complete exposition of the principles which underlie heat engineering. All are well printed, and the latter is abundantly illustrated. There are a few lapses on fundamental points, but they do not seriously interfere with the usefulness of the books for those who wish to know the "why" of things they see around them.

Plane Geometry: An Account of the More Elementary Properties of the Conic Sections, treated by the Methods of Co-ordinate Geometry, and of Modern Projective Geometry, with Applications to Practical Drawing. By L. B. Benny. Pp. vii+336. (London: Blackie and Son, Ltd., 1922.) 10*s.* 6*d.* net.

ON the whole, Mr. Benny's book is one that we would heartily recommend to the class of students he had in mind while writing it. It is not a book for beginners; it is not a book for mathematical specialists. But for the student who wishes to acquire a fairly competent knowledge of the methods of analytical conics, combined with the modern geometrical point of view, the book should prove very useful. The style is attractive, and the treatment interesting.

Mr. Benny's aim is clearly to combine the geometrical with the analytical treatment of conics. This aim is one that all should approve. The only fault we can find with the author's treatment is one that he himself mentions in the preface, namely, that there is a sort of see-saw between geometry and analysis in alternate chapters. This gives a rather unpleasant impression, and we must confess that when we first took up Mr. Benny's book the impression it made was a bad one. But continued study of the book showed that the fault is more apparent than real. Perhaps in a future edition Mr. Benny could so rearrange the material as to work the geometrical and the analytical into a really organic whole. S. B.

Electrical Engineering Laboratory Experiments. By Prof. C. W. Ricker and C. E. Tucker. Pp. xiv+310. (London: McGraw-Hill Publishing Co., Ltd., 1922.) 11*s.* 3*d.*

A STUDENT in an electrical engineering laboratory should be taught to rely on his own resources and encouraged to exert his own initiative. At the beginning of his course it is advisable that he perform rapidly under careful supervision the fundamental testing experiments. He should then be assigned work which requires a certain amount of originality. If he shows a particular interest in any problem, he should be encouraged to make a research on it. The teacher is occasionally rewarded by finding a keen and accurate observer who has the ability to analyse his experiments and draw useful conclusions from them. In the book under notice fifty-six experiments are given ranging from the wheatstone bridge to the mercury arc rectifier and from the direct-current generator to the load characteristics of a three-phase commutator motor. The theory given of the various tests is not too lengthy and can be easily understood. The book can be commended to teachers and students.

Practical Chemistry. By Dr. L. C. Newell. Pp. viii+543. (London and Sydney: D. C. Heath and Co., n.d.) 6*s.*

DR. NEWELL'S work is not a "practical" text-book in the English sense, but an elementary text-book of chemistry along the lines now followed in America. Industrial applications are kept in the foreground, and illustrations of technical plant are numerous.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Calculation of the Atomic Weights of Isotopes.

SOME months ago, when engaged on a study of radioactive disintegration series, the results of which appeared in the October issue of the *Philosophical Magazine*, I was able to formulate simple rules from radioactive data which enabled me to calculate a list of the atomic weights of the principal isotopes of both common and radioactive elements. This list, which will be published in due course, agreed closely, although not identically, with all the experimental values of the atomic weights of the isotopes of the common elements determined up to that date (June 1923) by Aston and others. Since then, in a recent issue of NATURE (September 22, p. 449), Aston has published some further results with which my predictions agree so exactly that I feel constrained to give here a brief account of how my list was arrived at, and to state some results which have yet to be verified or disproved experimentally.

The main supposition is that there are four separate radioactive series the members of which have atomic weights given respectively by $4n+3$, $4n+2$, $4n+1$, and $4n$, where n is an integer. In the paper mentioned above I give reasons for supposing that the first of these is the actinium series, the second the uranium series, the third a hypothetical series the end-products of which may be bismuth ($a=209$) and thallium ($a=205$), and the fourth the thorium series. It is known that in the uranium and in the thorium series successive changes are principally of two kinds: a succession of α-particles, and the succession α, β, β and α; it is probable, and I assume it to be so, that in the two other series the characteristic successive changes are a succession of α-particles and the succession α, β, α, β. I next imagine that radioactivity continues below the so-called end-products of the series, the uranium and thorium series being continued by the elements of even atomic number and the two other ones by the elements of odd atomic number. There is no experimental evidence for this, nor does it matter. The point is merely that isotopes, which on radioactive evidence would be presumed stable, would be found experimentally to be the isotopes of common elements, and those presumed instable (bodies which supposedly expel β-particles, for example) would not be found. This is reasonable.

An arrangement of this kind yields a surprising amount of information, and it may be claimed that solely from radioactive evidence the following points may be deduced: (1) It is probable, but not impossible, that isotopes do not differ by more than 8 units of atomic weight; (2) only end-products of radioactive series or radio-elements emitting α-particles should be considered when a comparison is made between common and radioactive isotopes; (3) all elements are limited to two isotopes of odd atomic weight (odd isotopes), and these differ by 2 units of atomic weight only; (4) odd elements (*i.e.* elements of odd atomic number) have odd isotopes only, and, if there be two, the lighter one is likelier to be the more stable and consequently the more abundant in Nature; (5) even elements may have both even and odd isotopes, but the former should be as a rule at least twice as numerous as the latter, and an odd isotope should not be either the lightest or the heaviest of all; (6) isobares of common elements may be of even atomic weight only; (7) an element the atomic number of which is given by $4n+3$ has an isotope of atomic weight $4n+1$, and *vice versa*; and (8) an even element has always one isotope a unit of atomic weight higher than one of the isotopes of the element next below it.

Several of the above rules have already been pointed out by Aston from his results on common isotopes. They are indeed the common ground of both ordinary and radioactive isotopes. They do not apply in their entirety to the elements below nickel and cobalt. It is not to be expected that the lightest elements with their simple structure would behave exactly like the heavier ones. In addition, it is probable from atomic weight evidence and certain evidence from Aston's results that the series $4n+2$ and $4n+1$ do not run continuously below the limit of cobalt and nickel.

If the radioactive evidence were decisive in regard to which mass-numbers are unstable, and which are possible isobares, the determination by calculation of all the isotopes of all the elements would not be difficult, but this does not appear to be so. The evidence does not give a complete solution because, among other things, I have not considered possible branching in any of the series. Branching no doubt occurs according to some plan, but up to date I have not discovered what that plan is. Consequently on one or two occasions I have failed to agree entirely with Aston's experimental results. For example, my calculations give two isotopes to calcium, 44 and 40, and two to argon, 40 and 36, but they indicate that 36 is the more abundant, whereas Aston's results (and the atomic weight) contradict this.

For the elements from hydrogen to yttrium my list is identical with Aston's list, which covers this range completely, except that I say that scandium has a second isotope at 47. Zirconium has an isotope at 92 and possibly a third at 94, but no others in addition to its principal one at 90 already established by Aston. Niobium has 93 and 95, molybdenum is simple and 96. Element 43 would have 97 or 99 if either existed, but they do not. (Presumably a missing odd element is one which occurs at a place where two successive odd mass-numbers happen to be unstable.) Ruthenium has 100, 101, 102, and 104, possibly 98, but not 106. Rhodium is principally, and probably only, 103. Palladium is certainly 104, 106, and 108, not 105 but possibly 102 and 110. Silver is as given by Aston. Cadmium is 110, 111, 112, 114, with perhaps 108 and 116, but not 106. Indium is 115 only. Tin and antimony are as given by Aston. Tellurium is mainly 128 and 126, with possibly 130 and 124 but not 122. (Were it not that 128 is greater than the atomic weight of iodine I should be inclined to say that, notwithstanding its atomic weight, tellurium was mainly 128.) Iodine and cæsium are simple as given by Aston. Xenon is as given by Aston, except that I drop 126 or 124. Lanthanum and præsodymium are simple, 139 and 141 respectively. It is more probable that cerium is simple and 140 than complex and 140, 142, and 144. Barium is complex, having 134, 136, and 138 but not; if cerium be simple, 140, and it has no odd isotopes.

The rare earths are not difficult to do in spite of the uncertainty of their atomic weights. Each of the even rare earths is complex. Element 61 would have 147 and 149 if either existed; europium is 151 and 153, holmium 163 and 165, and thulium 169 and 171. In spite of their atomic weights, terbium is 159 only and lutecium only 177. Hafnium is mainly

178 and 180 with some 182, and has no odd isotopes. Tantalum is 181 and 183, tungsten 184 only, and element 75 would have 185 or 187 if they existed. Iridium appears to have 191 as well as 193; platinum has 194 and 196, possibly 192, but 198 is unlikely. Mercury is 198, 199, 200, 202, and 204 and not 201 as Aston finds, but I cannot add 197 as he thinks possible.

Gold is 197 and simple if Aston is right about mercury; otherwise it should have 199 also. Thallium is 203 and 205, lead principally 208 and 206, the former in excess. Bismuth is simple and 209. Polonium is of course 210, and the only member of element 84 with a chance (and that a very remote one) of being isolated. Thorium is simple and 232. One isotope of element 89 is too unstable ever to be isolated. Element 91 has 231 and 233, the former being probably protoactinium. Uranium, which is complex, has been discussed in my paper in the *Philosophical Magazine*.

The order of intensity of the isotopes cannot be given accurately from these considerations, but a rough sorting into major and minor isotopes is not difficult to make. Mass-numbers which belong to no atomic number are difficult to estimate. At present I feel sure of ten even ones and thirty-one odd below polonium, most of which Aston has found. All but one of the former are of the form $4n+2$, and more than three-fifths of the latter of the form $4n+1$. There appear to be at least thirty simple elements if my predictions be added to Aston's certainties. Fourteen of these have accepted atomic weights within 0·05 of a unit, and as many fall short of a unit by this amount as exceed it. I have assumed Aston's whole-number rule in all the numbers given in this letter.

After these mass-numbers had been deduced I found that the complexity of an element was apparently a simple function of the atomic number $16n$. Thus there is a *probability* that elements of atomic numbers $16n+7$, $16n+10$, and $16n+11$ are simple; that $16n+3$, $16n+5$, $16n+13$, and $16n+15$ have two isotopes; that $16n+8$ and $16n+14$ have no odd isotopes; and that $16n$, $16n+2$, and $16n+12$ have odd isotopes. If this deduction be substantiated by experimental work it should throw light on the constitution and stability of the nucleus.

The Measurement of Very High Temperature.

IN 1914 Lummer [1] described some experiments on an arc burning in a gas at high pressure. His method of determining the temperature based on the increase of surface brightness of the positive crater is extremely unsatisfactory, and his figures, using his own values of surface brightness, appear to be nearly three thousand degrees too low. It seemed desirable, therefore, to repeat and extend the experiments and determine the temperature more precisely. A very accurate way of doing this would be to determine the ratio of the intensity of the light at two wave-lengths as far as possible apart, which would define the temperature if the positive crater were a complete radiator. This assumption need not be made if ratios of the intensities are determined at two different temperatures, one of which is known. Thus, for example, in the region in which Wien's law holds, if a_λ is a constant proportional to the emissivity, the intensity is given by

$$E_{\lambda T} = \frac{a_\lambda \cdot e^{-c/\lambda T}}{\lambda^5},$$

and

$$\log \frac{E_{\lambda_1 T_1} \cdot E_{\lambda_2 T_2}}{E_{\lambda_1 T_2} \cdot E_{\lambda_2 T_1}} = c\left(\frac{1}{\lambda_1} - \frac{1}{\lambda_2}\right)\left(\frac{1}{T_1} - \frac{1}{T_2}\right),$$

which determines T_2 in terms of T_1. Since a_λ, which may also contain the sensitivity of the measuring instrument, disappears from the final equation, this method is very convenient and may be made very accurate.

Two methods were used for determining the intensity, one by the use of a wedge as suggested by Prof. Merton,[2] the other making use of the photoelectric effect. The first method is more convenient in many cases; the second is probably more accurate.

The main difficulty is to make sure that one is really observing the hottest part of the crater. It is very difficult to keep the arc constant at high pressures, and obviously too low a temperature will be found if the arc shifts during the exposure so that part of the measurement is carried out on the colder parts surrounding the crater. If this has been avoided, comparison of the intensity at any two wave-lengths at atmospheric pressure and at high pressure enables the temperature at the high pressure to be calculated in terms of the known temperature of the normal arc. A check in the method is given by the constancy of the temperature found using various wave-lengths. The divergence from the mean is within the limits of experimental error.

Owing to the difficulty outlined above, observations at the same pressure do not repeat very accurately, though the highest values are fairly consistent. The following table summarises the provisional results for an arc in nitrogen:

Pressure in Atmospheres.	Temperature.
1	(4190)A
6	4680
18	6180
33	6520
80	8620

As already stated, these are minimum temperatures; and indications on one plate (10,000° at 50 atmospheres) seem to justify the suspicion that they may be considerably underestimated.

Further experiments making use of a number of improved methods are now in progress, and it is hoped shortly in a fuller publication to give more accurate values for the temperature of the crater as a function of the pressure and nature of the gas. The fact seems certain, however, that one can by this means reach temperatures in the laboratory considerably higher than the temperature at the surface of the sun.

It may be interesting to note here the strong reversal of some of the cyanogen bands shown on the plates within certain limits of pressure and temperature. The phenomenon is most noticeable between 30 and 40 atmospheres, and it should be possible to locate these limits more definitely in the course of the experiments.

I have in conclusion to acknowledge a deep debt of gratitude to Prof. Lindemann for much helpful criticism and encouragement.

[2] Merton and Nicholson (Phil. Trans. Roy. Soc. A. 217). Prof. Merton kindly lent me the spectrometer and wedge which he used in his own investigations, and I take this opportunity of thanking him for the loan of the apparatus and for his assistance in initiatin me into the details of his method.

Early Greek Chemistry.

It is generally recognised that chemistry began, as the "divine [or, perhaps, "sulphurous"] art" (*θεῖα τέχνη*) in Hellenistic Egypt, in Alexandria, during the first centuries of our era. The books of its practitioners have existed as copies in most European libraries for many centuries. Those in the King's Library at Paris were mentioned by Olaus Borrichius in the seventeenth century; parts of the most important were published and translated by Hoefer early in the nineteenth century, and the whole *corpus* was published, with a translation, by Berthelot and Ruelle as the "Collection des anciens alchimistes grecs," under the auspices of the French Minister of Public Instruction, in 1887–88, in four volumes. It is not a little surprising to find such an eminent writer on cognate subjects as Reitzenstein, as a result of admittedly hasty examination of the Paris MSS., offering rather severe criticism of the work of Berthelot and Ruelle, since the text of the latter is based on the collation of existing MSS., and not merely on those of Paris. The production of it and of the translation was a work of no small difficulty, as might have been anticipated from the place of origin and date of the original. A very large number of words have no place even in such exhaustive works as Du Cange's "Lexicon."

It is, therefore, particularly gratifying to find Prof. Stéphanidès, of the University of Athens, now undertaking a revision of the text and translation of the "Collection" in many places where they are obscure. His knowledge of chemistry, the literature of alchemy, and—particularly—of modern Greek, are brought into use. Mme. Hammer-Jensen, it is true, has recently attempted in her essay, "Die älteste Alchymie," Copenhagen, 1921, to reconstruct the theories underlying the Greek alchemical MSS., and to rearrange them in order of date. But her evident lack of broad chemical knowledge, and her approach from the way of the so-called "classical" philology, have noticeably hampered her contribution.

Prof. Stéphanidès' article, published in the *Revue des études grecques*, tome 35, No. 162, Paris, 1922, a copy of which he has just sent me, is one of great interest and value. The following may be mentioned as an indication of the type of emendation which he has been able to suggest—throughout with a full appreciation of Berthelot. Many words left untranslated are now given meanings, *e.g.* *χάνδρα* = "false pearl" in modern Greek. The explanation of the obscure passage given on p. 6 (206, 8) of Stéphanidès' paper is very ingenious. Some of Berthelot and Ruelle's translations read as nonsense, but in the hands of Prof. Stéphanidès the text reveals its meaning: "de la largeur d'un petit miroir très mince" becomes "en forme très mince de *pierre specularis* [mica]." The passage given by Berthelot and Ruelle as, "Quelques-uns après cela font boir un oiseau depuis le soir jusqu'à une heure, puis ils laissent mourir de soif le petit oiseau, en le privant de boisson," etc., is completely incorrect, and should read: "Quelques-uns donnent <les perles> à avaler à une poule <afin qu'elle les garde dans le gézier> depuis le soir jusqu'à une heure, en privant l'oiseau de boisson, et puis, en le sacrifiant, on trouve les espèces <les perles> brillantes." (Improvement of pearls by the action of the gastric juice: a well-known operation in ancient technology.)

There will be some criticism of such renderings as "*νιτρέλαιον* = acide azotique," and *Σαλόνιτρον ἤγουν σκευοβότανον* as "*βότανον* pour la *σκευή*," because "les Byzantins appelaient *βοτάνη* la poudre à canon et *σκευή* le canon." *βοτάριον* puzzled Hoefer; it has become fashionable to render it "magic plant." Some obscurities are put down to assonance, and belief in "sympathy" (cf. the *κρονος* and *χρόνος* of the Stoics).

The Musk Ox in Arctic Islands.

During my various arctic expeditions I have learnt a good deal about the ovibos (musk ox) from conversation with the Eskimos, and perhaps more from actual observation. Especially when we were in Melville Island (1916–17) we were in almost continuous association with the animal. It has occurred to me that what we know of the present habits and distribution of ovibos throws a light on one of the geological problems of the American arctic.

All my inquiries from the Eskimos and all the observations of our own party indicate that both herds and single animals move slowly—no faster ordinarily than strictly required by the feed. This means that in fertile arctic grass lands, herds move less than five miles a month. But—more important—we have neither observed nor heard about their crossing sea ice. We have never seen ovibos tracks more than one or two hundred yards from shore. It seems that, if they "thoughtlessly" start out upon the ice, they pause within 200 yards, look around for land, and turn in a direction where land is visible.

This means that, through observation and hearsay, I have concluded that the ovibos never cross from one island to another, either by swimming the water or by walking across ice. If this has always been their nature, we can explain their presence on several of the arctic islands only by assuming that once upon a time these islands were connected land.

Some of the arctic islands have numerous raised beaches and other indications that they have been rising rapidly in recent times—the Ringnes Islands, Borden Island, King Christian Island, and Lougheed Island. In none of these have we found any evidence that ovibos were ever present.

Since the living ovibos or remains of the dead are found, so far as I know, in all the other arctic islands, we must conclude that these islands were once upon a time connected with each other, either directly or by way of the mainland of either North America or Asia. It seems clear that the islands where ovibos have never been were at that time either separated by water channels from the land mass which later became the main part of the Canadian Archipelago, or else, and more probably, that they were then beneath the sea.

Scientific Names of Greek Derivation.

On looking through some arrears of Nature after the vacation I see, on August 18, p. 241, Dr. W. D. Matthew, in discussing the spelling of names derived from the Greek, asks if we should write "Deinosaur" or "Dinosaur"?

For the spelling it is no great matter, but it does matter for the pronunciation. For example, at one time it was customary, perhaps more or less may still be, to spell Pheidias "Phidias"; consequently, the unlovely pronunciation "Phiddias" was prevalent. So had we not better keep to Deinosaur?

The Problem of Leprosy.

RECENT progress, especially as regards treatment, has paved the way for practical advances in the control of the world-old problem of leprosy, so a brief survey of the position appears to be timely. Ancient records show it has been present in Africa and India, and probably also in China, from the dawn of civilisation. It spread over Europe during the first centuries of the present era, was carried to the New World soon after its discovery, and new epidemics originated in some Oceanic islands as late as the middle of the last century. There is evidence to show that leprosy is now spreading among the Mohammedan races of tropical Central Africa.

Nearly all the countries with the highest incidence of leprosy are situated in humid hot tropical areas of Africa, Asia, and America. Heiser not long ago estimated the lepers of the world at about two millions, which recent figures indicate not to be an over-estimate, as some authorities place the number in China at one million; the 1921 census figure for India is 102,513, with at least an equal number of earlier unrecorded cases, while the rates in very extensive areas of Central Africa have recently been shown to vary between 5 and 60 per mille, and in small areas have run up even to 200 per mille. These are terrible figures when we remember that the present official Indian rate is but 0·32 per mille, in spite of lepers being seen daily in the streets of most large towns of that densely populated country; South Africa has 2248 and the West Indies 1433 known lepers, so the total number in British countries cannot well be less than 300,000. The eradication of the disease is thus a formidable task.

During the latter half of the nineteenth century a remarkable controversy raged between the supporters of the hereditary and contagious theories of origin of the disease. The hereditary view had for a time supplanted the ancient belief in its contagiousness, although the classical figures in support of the hereditary transmission of leprosy in Danielssen and Boeck's book of 1848 have long been shown by advancing knowledge to lend no valid support to that theory. The theory rapidly lost ground after the discovery of the lepra bacillus by Hansen in 1874, and is now finally discredited in favour of the age-long theory of the communicability of the disease. Jonathan Hutchinson's fish theory, also of prebacteriological origin, has had no supporters since his decease.

The precise manner in which the causative bacillus of leprosy passes from the diseased to infect the healthy is still, however, not finally proved, although there is a very general consensus of opinion that it enters through minute lesions of the skin or superficial mucous membranes, especially the nasal, and that prolonged exposure to close contact with a leper is usually necessary before infection takes place. In a series of 700 cases in which the probable source of infection was traced, house infection was shown in about 80 per cent., while in at least 30 per cent. the unfortunate victim had slept in the same bed as a leper before contracting the disease. It is also known that the nodular form is far more infective than the nerve type, owing to the extensive discharge of the lepra bacilli from the ulcerated skin and nasal lesions of the former. Children and persons not over twenty years of age are far more susceptible than those of thirty years and upwards. All these are very important points from the prophylactic side.

The three international leprosy conferences of 1897, 1909, and 1923 have all endorsed the contagiousness of the disease and the necessity of segregation in stamping out or greatly reducing it, as has been so successfully carried out in Norway, where 2833 cases in 1856 have been reduced to 140 at the present time, while during the last two decades the rate per mille has been reduced to less than one-half the former rate in Cyprus and Jamaica through similar measures, the value of which when practicable is undoubted. Unfortunately the expense of compulsory segregation is entirely prohibitive when such large numbers as those of India, China, and Central Africa have to be dealt with, while, even under the favourable conditions of Norway, as compared with backward and poor tropical countries, the time required to eradicate the disease is much prolonged by the impossibility of discovering and isolating the cases in an early stage, as long as this involved life-long separation from relatives and friends with no appreciable hope of recovery and restoration to their homes. The inevitable result is that by the time many of the patients were detected and isolated, other members of their households were already infected, though they develop the disease only after several years, on account of its prolonged incubation period.

Advances in the Treatment of Leprosy.

It is a remarkable fact that, just as the great specific remedies for malaria and amœbic dysentery, cinchona bark and ipecacuanha root respectively, were discovered centuries ago by the aboriginal South American Indians, so the one remedy of value in leprosy, chaulmoogra oil, is an old Hindoostan medicine. It was brought to the notice of European practitioners in 1853, and was shown by Ralph Hopkins of Louisiana to be able to clear up a certain proportion of incipient cases, although it only retarded the advance of typical ones, being too nauseating to allow of more effective use by the oral route.

Intramuscular injections of the oil proved to be more efficient, and in 1913 Victor G. Heiser reported 11 per cent. of apparent cures after some eighteen months of painful injections, which only a certain number of lepers will submit to. These observations led Rogers to search for a soluble preparation of the active portion of the oil more suitable for injection purposes, which he found in 1916 in the sodium salts of the different fractions of the unsaturated fatty acids of chaulmoogra and hydnocarpus oils derived from *Taraktogenos kurzii* and *Hydnocarpus wightiana*. First the lower melting-point fractions were used under the name of sodium gynocardate, while afterwards he concluded that

sodium hydnocarpate was more active than either the former or than sodium chaulmoograte. E. L. Walker and Marion Sweeney confirmed these observations and showed that these fractions had a direct lethal action on acid-fast bacilli as a class when added to cultures. This led them to suggest a direct action of the drug on the lepra bacillus *in vivo*.

As these soluble preparations were still painful and slow in their action, Rogers commenced to use them intravenously, when he observed occasional severe febrile reactions with inflammation of leprous nodules accompanied by extensive breaking up of the lepra bacilli in them, followed by gradual absorption and eventual disappearance of both the bacilli and all signs of the disease. The same worker next showed that a soluble sodium salt of the fatty acids of codliver oil, sodium morrhuate, and of soya-bean oil (sodium soyate) were also effective in leprosy, although they had no direct action on acid-fast bacilli *in vitro*. More recently, he has found an increase in the amount of lipase in the blood of treated cases, and Muir in Calcutta has shown that this ferment decreases after a severe general reaction, indicating that it has been used up during the destruction of the bacilli in the body.

Shaw-Mackenzie showed these soaps to stimulate the action of pancreatic ferment *in vitro* on fats; so Rogers has suggested that they may act through the lipase, dissolving the fatty coating of the lepra bacilli *in vivo*, much as Dryer has succeeded in doing *in vitro* in the case of the tubercle bacillus, a point of practical interest also in connexion with the use of sodium morrhuate in tuberculosis, which is still under trial. In the case of leprosy large numbers of the bacilli may be safely disintegrated by the treatment with apparent enhancement of the resisting powers of the patient's system, complete disappearance of extensive nodular leprosy having occasionally followed a very severe febrile reaction of a month or more in duration, followed by gradual clearing up of the disease during the following year without any further treatment. Moreover, K. K. Chatterji has obtained an active preparation against leprosy from mim oil, and Muir others from linseed and even from olive oil, so an immense field has been opened up for further search for possible curative products against both leprosy and tuberculosis.

In 1920 Prof. Dean and Dr. Hollmann in Honolulu made a further practical advance when they showed that ethyl ester chaulmoogrates and hydnocarpates can be successfully used by the intramuscular method in place of the more troublesome intravenous injections of the sodium salts. Similar preparations to theirs were the basis of "leprolin" issued by a German firm several years earlier and used with some success in leprosy by Engel and others.

Reports from all parts of the world now suffice to prove that an important advance has been made in the treatment of leprosy by these various researches, the less advanced cases being naturally more amenable to the treatment, and although in such a chronic disease as leprosy, with a very long incubation period, it is difficult to decide if actual cure can be brought about any more than in tuberculosis, yet a few of the earlier Calcutta cases have now remained free from active signs of the disease for from five to eight years. There is good reason, therefore, to hope some are actually cured, while there is no doubt the infectivity of the disease is removed in many of the earlier cases, with consequent decrease of possible contagions from them.

Provision for Treatment.

The practical question now arises as to how far the improved treatment can be utilised in the struggle against leprosy. The third International Leprosy Conference at Strasbourg in July last endorsed its value, and laid it down that segregated lepers should be provided with the best treatment. Only a very small percentage of the total lepers segregated in India and other British-governed countries are receiving its benefits, however, much less the vastly greater numbers of free lepers, including most of the earlier amenable cases, the infective powers of which might be largely abolished by six months' to a year's treatment. The treatment would cut short the new infections arising from them among their relatives and others living in their houses, and solve the hitherto unsurmountable problem of dealing effectively with the early cases of the disease, which it is often impracticable to segregate. It affords the only hope of a rapid diminution of leprosy in India, Central Africa, and other countries with very numerous lepers.

For this purpose, in addition to agricultural colonies for indigent and especially dangerous lepers, it will be necessary to organise out-patient leprosy clinics in connexion with as many hospitals as possible, where the weekly injections can be given, on the plan developed by E. Muir at the Tropical Disease Hospital. Here about 100 cases are under regular treatment, and much research work is being done with the view of improving further the treatment in the leprosy laboratory of the Calcutta School of Tropical Medicine. By this means it should be possible to render a large number of the earlier cases non-infective at a far lower cost than in settlements, and to produce a decline of new infections, and ultimately in the incidence of leprosy, hitherto impossible to obtain.

Unfortunately, it must in truth be admitted that the United States is doing far more for its lepers in the Philippines and Hawaii, both as regards segregation and in applying the newer treatment, than Great Britain is for her much greater number of lepers, mainly due to lack of funds, especially in India and Central Africa. During the last few months, however, a British Empire Leprosy Relief Association has been founded under the chairmanship of Lord Chelmsford, with the support of a number of leading British physicians and men of science, which will shortly attempt to raise the large sums necessary to remove this reproach from the British nation. This has become all the more imperative now that the Strasbourg Leprosy Conference has pointed out the obligation we are under to provide the best treatment for our segregated lepers. It applies equally forcibly to the free, earlier, and more curable cases, and it is to be hoped that no further time will be lost in bringing the knowledge that science has now furnished to the relief of those who are perhaps the most cruelly afflicted of the human race.

L. R.

The Geographical Position of the British Empire.[1]

By Vaughan Cornish, D.Sc.

The Position which has been occupied.

The British Empire, although situated in every continent, with shores on all the oceans, is seen to have a definite geographical position when we consider the ports of call which unite its lands and the naval stations which guard the communications. During the growth of the Empire eastward and westward from Great Britain, numerous harbours were held at different times, those retained being a selection unrivalled by the ports of any other State in commercial and strategic position.

The naval station of Bermuda, well withdrawn from aerial attack, has a central position in the great western embayment of North America intermediate between the ocean routes which connect Great Britain with Canada and the West Indies. No foreign ports flank the route between Canada and the west coast of Great Britain. At the western gateway of the South Atlantic we have excellent harbourage in the Falkland Isles. Malta, the capital of our fleet in the Mediterranean, has a commanding position at the straits which connect the eastern and western basins, and the naval station at Gibraltar helps to ensure the junction of the Home and Mediterranean Fleet and to protect the Cape route. The British army which is kept in Egypt as garrison of the Suez Canal ensures our use of this gateway so long as we can navigate the Mediterranean. If that navigation be interrupted we can still oppose the seizure of the Isthmus, for we are able to send reinforcements by way of the Red Sea. East of Egypt the British island of Perim stands in the Straits of Bab-el-Mandeb, and the garrisoned fuelling station of Aden provides the necessary port of call on the routes to Bombay and Colombo. Colombo, in the Crown Colony of Ceylon, is at the parting of the ways for Australia and the farthest parts of our Asiatic possessions, and Singapore stands at the narrow gateway of the shortest route between India and the Far East.

The Cape route to India and Australasia is improved by British ports of call in Sierra Leone, St. Helena, and Mauritius, and is more effectively dominated from British South Africa than at first appears, for although there is open sea to the south there are no useful harbours in the Antarctic continent, and on the African coasts the harbours are under British control for a thousand miles from Cape Town.

Of the six great foreign Powers, the French alone are posted on the flank of both routes between Great Britain and the Indian Ocean, and no Great Power has its home territory on that ocean. Thus the principal lands of the British Empire—Canada, the British Isles, South Africa, India, and Australasia—have good communications with one another across the Atlantic and Indian Oceans both in peace and war.

The conditions of strategic communication across the North Pacific, on the contrary, are adverse to us, owing mainly to the circumstance that we opened up British Columbia across the prairies and by the coasting voyage. Had our colonising route been across the Pacific, the Hawaiian Islands, which were first brought into touch with the Western world by the ships of the Royal Navy, would have been a British settlement and one of our first-class naval stations. As things happened, however, these islands were first needed by the Americans, and now form the essential western outpost of the United States navy. Between them and British Columbia the ocean is empty of islands, and Fanning Island, south by west of Hawaii, with the adjacent small coral islands in our possession, are no adequate substitute, even apart from overshadowing by a first-class naval station in the neighbourhood. Thus there is no good strategic communication between Australasia and Canada across the North Pacific. In this connexion it must be remembered that cousinship does not relieve the American Government from the obligations which international law imposes upon neutrals. It was not until three years after the outbreak of the War that America could offer us any facilities in the harbour of Honolulu which were not equally open to Germans. It must also be noticed that we have no control of the Panama route between New Zealand and Great Britain.

Turning to the question of communication between British Columbia and India, it is important to realise that the Pacific coasts of North America and Asia are in a direct line with one another, forming part of a Great Circle, so that there is no short cut across the ocean, as the map misleadingly suggests. Thus the course between Vancouver and Hong Kong is not only very long, but also closely flanked by the home ports of Japan, so that its security in time of war depends upon the attitude of the Japanese.

When, therefore, we differentiate the routes on which we have well-placed naval stations and recruiting bases from those dominated by the ports of some other Great Power, we see that the lands of the Empire are united by the Atlantic and Indian Oceans and strategically separated by the North Pacific. Thus the form in which the Mercator map is usually drawn by British cartographers with Canada in the upper left and Australasia in the lower right corner is a good representation of our maritime Empire, for it shows the countries as connected across the Atlantic and the Indian but not across the Pacific Ocean.

Upon this map a symmetrical distribution of our lands is revealed when a Great Circle is drawn connecting Halifax in Nova Scotia, the eastern terminal port of the Canadian Pacific Railway, with Fremantle, the western terminal port of the Australian railway system. This truly direct line is twisted on Mercator's map into the form of the letter S. The line passes through Lower Egypt close to the Suez Canal following the general direction of the Main Track of the Empire, which is the steaming route from Canada to Great Britain, and thence by the Suez Canal to India and Australia. At one end of the line lies the Canadian Dominion, and at the other Australasia, to the north the British Isles, and to the south the Union of South Africa, the chief homes of the British nation. Our

[1] From the presidential address delivered to Section E (Geography) of the British Association at Liverpool on September 13.

coloured peoples are also distributed symmetrically about the line, India being on the east, the Crown Colonies and the Protectorates of Africa on the west, so that it is the axis of symmetry of the Empire. Not far from its middle point is the Isthmus of Suez, where our direct line of sea communication is crossed by the only continuous route for the international railways which will connect our Indian and African possessions, and adjacent to the Isthmus is the central station of our airways.

Such is the form and position of the British Empire, regarded as a maritime organisation, which in fact it is.

The Empire thus mapped has an intermediate position among the commercial, national, religious, and racial communities of the world such as is occupied by no other State. The ocean routes must always be the link between the two great land areas of the world, and in the present state of land communication provide the connexion between the numerous independent systems of continental railways. The chief of these systems is based on the ports of continental Europe, of which the greatest communicate with the ocean, and therefore with other railway systems, by way of the English Channel. Thus the island of Great Britain is intermediate between the principal termini of the European railways and the other railway systems. Its harbourage is unequalled by that of any country of continental Europe, and its supply of shipbuilding material and coal exceptionally good. Thus the physical characters of the island accord with its position on the commercial map, and the metropolitan British in their intermediate position have become the chief common carriers of international commerce.

The Suez Canal, where we have the principal control, is the gateway between the railway termini of Europe, the greatest manufacturing centre of the world, and those of the monsoon region of Asia, the greatest centre of population. It is also on the shortest route between the railways of North America and India.

How far-reaching is the effect of our intermediate position is strikingly suggested by the fact that it is the British naval stations which would, if available, provide America with the best line for reinforcement of the Philippines, the Achilles heel of the Republic. The distance of Manila from the naval shipbuilding yards of the United States is almost exactly the same by Panama and Suez, but the Pacific connexion is bad, owing to the great distance between the stations of the American Navy. The relation of Port Said and Singapore to America and the Philippines is only one of many cases in which our position is intermediate between the home and colonial possessions of a white nation. Thus the important French possession of Indo-China has to be reached from France either by way of the Suez Canal where we maintain a garrison, or by rounding the Cape where we have a national recruiting base, as well as a station of the Royal Navy. The true significance of our intermediate position has, however, been generally missed owing to a one-sided interpretation of strategical geography. An intermediate station, particularly a naval station, has commonly been regarded as a blocking position, a barrier where freedom of movement can be interfered with. The historical fact is, however, that the harbours of the British Empire have also been a link between nations. In the War the British Empire was the link of the allied and associated powers, and its geographical position is unequalled for making a benevolent alliance effective or for checkmating the action of an alliance formed with a sinister purpose.

The British Empire provides in Canada the one link on the political map between the European and American divisions of the white race. Of the 1650 million people in the world, the whites number about 500 and the coloured 1150. The former are mainly grouped on the two sides of the North Atlantic Ocean; of the latter, the greater part, about 800 million, are in the monsoon region of Asia, which includes India, Indo-China, China proper, and Japan.

In tropical Australia the British, in the exercise of their discretion, have set up a barrier between the white and coloured races. The problem of Australian settlement is complicated by the circumstance that the northern coast-lands lie in the Tropics, and have a climate which makes field work very arduous to white men. It is, moreover, uncertain if British families would continue true to ancestral type in this climate. If, however, settlers from the neighbouring monsoon lands of Asia be admitted, it would be impossible to maintain a colour line between tropical and temperate Australia, and the labour of the Commonwealth would in time be done by coloured people. The Australian British are far from the main body of the white race and from Great Britain, the chief recruiting base of their own nation. On the other hand, the distance by sea between Townsville, Queensland, and the Japanese coast is no longer than the course of the coasting steamers from Fremantle to Townsville; and the other lands of monsoon Asia are even nearer than Japan.

The relations between geographical environment and national welfare indicate that the decision to erect a barrier against coloured labour in tropical Australia is best both for the white race in Australia and for the coloured people of the monsoon region of Asia. The admission of coolie labour would deteriorate the national character of the Australians, for the greatest nations are those which provide their own working class. The descendants of the Asiatic coolies would on their part have a stunted existence as a community unable to share fully in the national life of their new land, yet cut off from the main body of their own people. Far better, then, that the Asiatic coolie should remain where the family life of his descendants will be part and parcel of national life.

Neither should it be assumed that there is not room in Asia for a large addition to the population. The pressure of population in China is largely due to the undeveloped condition of mining, factories, and communications. The coal-fields are unsurpassed in the world, and iron ore is abundant; if they were worked, and factories were based upon them, the new occupations and improved market for agricultural produce would provide at home for many of those who now migrate overseas. The further development of manufacture in India would operate in the same direction. The growth of a manufacturing population in China and India would stimulate cultivation and stock-rearing in the sparsely inhabited region under Asiatic

rule which runs diagonally across the meridians from the Persian Gulf to the Amur, and includes the eastern provinces of Persia at one end and Mongolia and Manchuria at the other. This has for the most part a light rainfall, but comprises much fine prairie country and some good agricultural land, while in the more arid tracts there are many great rivers fed from snow-fields and glaciers which could be made to irrigate large areas.

Adjacent to the Indo-Chinese peninsula are the East Indies, the climate of which is suited both to Indians and Chinese, with great tracts of undeveloped land the productivity of which is attested by luxuriant forest. The sparsely peopled regions of Asia near to India, China, and Japan by land and sea, and for the most part connected with them by ties of civilisation, provide an area for the overflow from these countries which is more than twice as large as tropical Australia and British Columbia, together with California, Washington, and Oregon, the American frontier provinces of English-speaking labour.

India includes one of the most important borderlands within the Orient, that of the Mohammedan and Hindu worlds. The Punjab, with its great rivers and plain, is in such striking contrast to the mountains and plateau of Iran that we are apt to lose sight of the fact that, climatically, it more resembles the highland on the west than the rainy valley of the Ganges on the east. It is an eastern borderland of Islam, a religious world which is mainly comprised in the belt of dry country which stretches diagonally from the Atlantic shore of Morocco to the Altai Mountains. Delhi, under the Great Moghul, was an advanced capital of the Mohammedan world just within the Ganges valley, which is the headquarters of Hinduism. In this sub-imperial capital the two antagonistic civilisations are now linked to the government of Great Britain, and the age-long wars between them have ceased.

Up to the time of British predominance, India was the terminal position of continental conquerors unused to the sea, who did not develop the advantages of a salient maritime position. The ports of India lie conveniently for a long stretch of coast-land on the great gulf which forms the Indian Ocean, and now, owing to the facilities provided by British shipping, much of this coast-land has easier communication with India than with its own continental interior. Several British possessions in the parts of Africa adjacent to the Indian Ocean are in the intermediate position between the principal homelands of the black peoples and the overflowing population of India, and nowhere has the responsibility of our intermediate position called for more careful examination of the rights and interests of competing coloured races. The decision with reference to Kenya which has just been given by the Home Government recognises the main physical regions in the coloured world as political divisions of the Empire within which the established races have special rights, which it is our duty to safeguard.

From the foregoing facts it is clear that the British people, metropolitan and colonial, are in a greater degree than any other nation the doorkeepers of the world in respect of economic, strategic, and racial communications.

The Consolidation of the Position.

The consolidation of the geographical position which the British nation has won turns upon the future of colonisation within the Empire. The ratio of white to coloured people in the Empire is only about one to six. The former are mostly of British stock. The latter are of many stocks, differing physically from each other as much as from the white people, and belonging to diverse religions. Their numbers are steadily increasing under British rule. Consequently, if the Empire is to be guided by the British, the numbers of our race must also increase. There is, however, a school which considers that if our ideals of ethics and efficiency are once accepted by the coloured peoples, the racial complexion of the Empire will be unimportant, as public affairs will be regulated by our principles. This proselytising point of view does not take account of the contingency that British ideals implanted in coloured stock may receive alien development in future generations owing to biological causes. Our confidence in Western culture in general, and the British version of that culture in particular, is based more upon the power of adaptation which it has shown in our hands since the Renaissance and the era of oceanic discovery than upon any system of which we can hand over a written prescription. It is only in our own national communities, mainly composed of British stock, with minorities nearly akin, that we can be confident that British ideals will develop typically in the way of natural evolution. Therefore in our own interests and in that of the coloured races (who conflict among themselves) it is desirable to maintain the present proportion of the British stock, to whom the Empire owes the just administration of law and a progressive physical science.

We have to note that the population of Great Britain, which is now forty-three million, outnumbers the combined population of Canada, Newfoundland, South Africa, Australia, and New Zealand in the proportion of two and a half to one, and increases more rapidly than that of all these Dominions. Thus the chief source available for the British peopling of the Dominions is the metropolitan, not the colonial, population.

The number and density of the population of Canada is exceeded in the proportion of about ten to one by the white population of the United States, hence it is inevitable that there should be a large flow of people from the latter country to the Dominion. As it is essential to unanimity in the Empire that the Canadians should continue to be British in sentiment and not become pan-American, a large immigration from Great Britain is required in Canada. Moreover, the population of continental Europe outnumbers that of Great Britain in the proportion of something like ten to one, and as emigrants go to Canada from many European countries there is a further call for British immigrants to maintain the British character of the Dominion.

The co-operation of the Union of South Africa in the War only became possible after the failure of an insurrection by part of the Boers. Since the number of persons of Dutch and British stock is about equal, an influx of British colonists is required in order to ensure unanimity between South Africa and the rest of the Empire.

The population of Australia stands to that of Japan as about one to ten. The Japanese are a patriotic as well as an advanced nation, and claim equality with the white nations from patriotic motives. It is evident, therefore, that a strong reinforcement of British population is needed to maintain the doctrine of a white Australia. For the same reason New Zealand also needs emigrants, since Australasia is strategically one.

But what are the needs of Great Britain? There is a school which teaches that we should be strategically safer if we had no more people than our farms can feed, which would be about one-half of our present population; that we have passed the number which can ever be supported here in comfort; and that additions to the population would deteriorate its quality by packing the slums. The same school contends that emigration, by taking the best and leaving the worst, will produce a disgenic effect in the home country. The conclusion is that the salvation of Great Britain can only be ensured by a drastic reduction in the size of the working-class family. The strategic argument used by this school is out-of-date, as the proper plan of campaign for a combination of Powers bent on breaking up the citadel of the Empire is not naval blockade but aerial bombardment, and what the country now needs for its defence is a great development of technical industries and therefore a large population. A rural Britain would be quite unable to defend itself.

The economic argument shows too little appreciation of the permanent commercial advantage of our geographical position. As soon as the world gets again into its stride, conditions in Great Britain will improve, and thereafter each increase in the population of the world outside will provide more work in this country since our geographical position is unsurpassed for rendering economic service to other nations.

The common notion that we are packing the slums is contradicted by the census. Taking the case of the Metropolis, not only is central London less closely peopled than formerly but the five rural counties round London contain a million residents who were born in London and have spread out into the countryfied surroundings.

Neither does the census support the loose assertion that the towns are unable to replenish their population without fresh blood from the rural districts. The proportion of London residents who are London-born has steadily increased throughout the last forty years, and the birth-rate in towns is as high as in rural districts even when corrected for the effect of migration between them. Happily, also, the opinion formerly current that the townsman was deficient in morale was refuted by the War, in which our urban regiments showed a sustained valour which has seldom been surpassed in the long annals of military history.

The contention that selection for emigration will leave us only the worst, ignores the essential consideration that the best youngster for the Dominions is not necessarily the best for the Home Country. Here we need lads with sufficient business tenacity to resist the restlessness of youth quite as much as the Dominions need those who have a taste for frontier life.

The unequal distribution of men and women as between Great Britain and the Dominions limits the marriage-rate and consequently the total birth-rate of the British throughout the Empire in a way to which no other nation is equally subject. The excess of women in Great Britain cannot, however, be wholly paired in the Dominions unless the exodus of men to the United States be largely re-directed to our own lands.

Now that the limitation of the family is year by year determined more by choice and less by chance, it is important that all should know the size of family which is necessary for increase of the race. Taking account of the present age of marriage and the number of deaths before that age, I find that a general preference for the family of three would not quite maintain our numbers in Great Britain even if all migration ceased. If, therefore, the size of family be universally decided by choice the number of the race cannot be maintained, far less increased, under present conditions unless those who enter into matrimony cherish the ideal of a family of four children. Upon this, more perhaps than upon any other factor, depends the continued efficacy of the British Empire for guiding backward races, enlarging international commerce, and restricting the range of war.

The Sun and the Weather.

A RECENT article by C. G. Abbot and his colleagues of the Smithsonian Astrophysical Observatory (Washington: Proc. Nat. Acad. Sci., vol. 9, 1923, No. 6, p. 194) directs attention to a remarkable decrease in the amount of heat radiated by the sun during 1922 and the early months of 1923. This amount, the so-called "solar constant," has been well below its average value since the beginning of April 1922. No such outstanding sequence of low values has been found since the beginning of observations in 1905, and if the sun's variation influences terrestrial weather, 1922 and the early months of 1923 ought to show this influence. If the temperature of the earth's surface were determined directly by the amount of solar radiation, this long-continued deficiency would give rise to a general fall of temperature by 2° or 3° F. Owing to the complexity of the atmospheric circulation, no such simple direct response is to be expected, but we may reasonably look for anomalous weather, and in fact the winter of 1922–23 appears to have been unusually disturbed in North America. In different districts there were extremes of both heat and cold, drought and rainfall, and the authors remark that "while it is far too early in the study of the relations of solar radiation and weather to state that the extraordinary solar change caused the unusual winter weather, it does no harm to draw attention to both."

If we turn to Western Europe, we find similar disturbed conditions, especially in the north, while the Arctic Ocean has been characterised by low pressure and abnormally high temperature. The coincidence with low solar radiation may be remarked, but it is

difficult to trace any actual connexion between the two. The most that can be said at present is that both in North America and Europe the storm tracks lay for the most part rather far north. During sunspot minima, which are usually associated with low values of solar radiation (as in the present instance), a similar northward displacement of the storm tracks has been remarked, and in fact has been made use of by Huntington and Visshcr in their theory of climatic changes (Nature, vol. 111, 1923, p. 561). The solar effect, however, is difficult to trace because of the great complexities introduced by terrestrial conditions, and particularly by the movements of Arctic ice. For example, the anomalous weather of May last in the British Isles has been traced back to ice movements and variations of North Atlantic currents set on foot in 1921 and the early months of 1922 (*Meteorological Magazine*, June 1923, p. 100), that is, before the decrease of solar radiation had set in, though of course the latter may have played some part in it. It will be possible to analyse the effects of the decrease in greater detail when the volumes of the "Réseau Mondial" for 1922 and 1923 are completed, since this publication gives the deviations of temperature from normal at a large number of stations distributed over the globe.

Current Topics and Events.

The resignation of Prof. A. G. Green from the post of chief research chemist to the British Dyestuffs Corporation is followed by the announcement that Prof. W. H. Perkin has been appointed advisor to the headquarters research staff of the Corporation. This notice is reminiscent of a statement published in the *Times* of February 11, 1916, to the effect that "Prof. W. H. Perkin, F.R.S., of Oxford has been appointed to conduct the Research Department of British Dyes (Limited) and he has also accepted the Chairmanship of the advisory council of the company." Taking these two notices in conjunction, it does not appear that the recent one entails any material change in the relationship between the Waynflete professor of chemistry in the University of Oxford and the British Dyestuffs Corporation. Meanwhile the Corporation has in quick succession lost the whole-time services of Prof. Robinson, Dr. Herbert Levinstein, and Prof. Green. Moreover, in his last report to the Corporation, the chairman of the merger company intimated the directors' belief that "further economies can be effected in our research department." It will be of interest to note the attitude of the reappointed advisor towards the impending diminution in the research staff. Although the 400,000*l.* spent in research during four years is a considerable sum, yet it is probably less than the expenditure on trained chemists incurred by the pre-War forerunners of the Corporation, taking into account the much smaller capital sum at the disposal of these firms. The chemical staff of the Corporation is smaller considerably than that of any of the larger units of the Interessen Gemeinschaft. If, therefore, the Corporation is to compete successfully against its foreign rivals, further economies as regards chemists are very undesirable; for without ample technical assistance, the Corporation cannot fulfil the purpose for which it was founded with very substantial financial assistance from the Government, namely, with "the primary objects of supplying dyes and colours to those British trades which depend for their continuance on their ability to obtain them."

The "light plane" trials at Lympne have demonstrated the possibility of man-flight with 3 horse-power engine. Two aeroplanes tied in the principal test for fuel economy, with 87·5 miles to the gallon. The former had a 3½-6 h.p. engine, a speed of 55 m.p.h., and a mileage for the week of 362; the latter 5½-10 h.p., 74 m.p.h., and 775 miles, to which must be added a winning climb to 14,400 ft. The decisive value of excess power is thus shown. The cost of light planes built singly is about 500*l.*, and the competing machines were handled by the most experienced pilots in the country, while Maneyrol, perhaps the most brilliant pilot present, met with fatal accident, thus reminding us that flying still has its special risks. It would, therefore, be rash to conclude that flying is now cheap, easy, and entirely safe, but in spite of these cautions the results achieved will stimulate flying in many directions. The Director of Research indicated one of the most interesting of these in remarking that trials on light planes could be applied to geometrically similar aeroplanes of the largest size. There is a fairly satisfactory theory of similar aeroplanes, but the best type is being slowly evolved by the efforts of designers and the criticisms of pilots. What is suggested is that it is possible to investigate the relative merits of different types on the scale of the light plane at comparatively small expense, and then to apply the results to the largest aeroplanes, which have proved enormously expensive in development by direct methods.

An account of the investigation of a prehistoric flint mine at South Down, about three miles north of Chichester, was given by Major A. G. Wade at a meeting of the Prehistoric Society of East Anglia held at Burlington House on October 10. Major Wade has identified twenty-one circular depressions, averaging about 12 ft. in diameter, running along the summit of the Down in a straight line from east to west. Three of these, on excavation, proved to be mine-shafts sunk in the chalk for the purpose of extracting flint-nodules. The first shaft measured 12 ft. in diameter and 15 ft. in depth, and the second 9 ft. in diameter and 9 ft. in depth. Although no galleries were found, the first shaft was deeply undercut on one side where the miners had followed a vein of flint. In this shaft a pick made from an antler of red-deer, similar to those found at Grimes' Graves and Cissbury, indicated the method employed in mining. A large number of implements of Aurignacian type was found in the infilling of the shafts, and in the second the top-stone of a saddle quern of green sandstone. A large elongated axe is regarded

by Mr. Reginald Smith as identical with a late Acheulean form. The discovery is one of considerable interest, as the pits are in all respects comparable with those at Cissbury, while if the type of the implements is accepted as evidence of date, they support the view that both mines are of palæolithic age. The quern stone, unless it can be shown to be later than the implements, would then suggest a much earlier date for corn growing than is usually accepted. The excavations were carried out with the permission of the Duke of Richmond, by whom the implements, mollusca, and animal remains have been presented to the Brighton Museum.

THE *Publishers' Circular* for September 1 contains some suggestive remarks by Mr. T. W. MacAlpine on "Scientific Literature: the Need for Co-ordination." Their gist is that publishers, who cannot be expected to know the requirements of every branch of science, might welcome advice from a committee or committees of scientific workers such as might be appointed by the British Association. Among the points to be specially considered are form and style of treatment, degree and nature of illustrations, uniformity of nomenclature and symbols, size of page and of printed area, selection of type, division into chapters, paragraphs, etc., and the numbering of them, list of contents, and index. Though we hold the view that too much standardisation often checks improvement by hindering natural selection, still we think some steps could well be taken along the path sketched by Mr. MacAlpine. He is perhaps not aware that there already exists a committee of the British Association appointed to advise on similar matters in special reference to zoology and the allied sciences. The last report of this committee, presented at the Liverpool meeting, deals with some questions that directly concern publishers. One of these is the precise and correct dating of volumes and parts. The other, discussed at length, is "What constitutes Publication?" The answer is summarised thus: "Publication of a new systematic name is effective only when the volume, paper, or leaflet in which it appears is obtainable at a price in the way of trade by any applicant, or is distributed widely and freely to circles interested, it being always of a character suitable to the publication of such matter."

AT last Lyme Regis has a museum and the beginnings of a type collection of the fossils for which it is famed. The desirability of such a collection has been felt by some of the residents for many years, but the question of cost has blocked the way. In 1901 the late Mr. T. E. D. Philpot, a landowner at Lyme, erected a suitable building, but the Town Council did not see its way to find the necessary funds to maintain it, and the fabric stood empty and forlorn. Attempts to revise the situation were made early in 1914 and Mr. Philpot was approached in the matter, but the movement was abruptly ended by the outbreak of War. On Mr. Philpot's decease, two years ago, his representatives renewed his offer to the Town, and this time the Council was persuaded to accept the handsome gift. Fortunately, an enthusiastic palæontologist, Dr. Wyatt Wingrave, was ready to act as honorary curator and to lend his own private collection of local fossils. These, with a few from other sources, form quite a respectable nucleus around which all geologists will be glad to see the growth in Lyme itself of a collection worthy of the world-wide reputation of the place. The annual report shows what a good beginning has been made and includes the usual appeal for funds, for cases, and for gifts of specimens, all of which should be forthcoming now there is a place to put them and a curator to watch over them.

IN the September issue of *State Technology*—the journal of the Institution of Professional Civil Servants—the Act of the United States Congress of March last classifying civil servants is published in full. Its principal interest for us is the prominent position it gives to the professional and scientific civil servant. In Great Britain, the administrative heads of government departments, even when their concern is mainly with scientific or technical matters, are men with a classical or literary education and no scientific or technical knowledge, and the Institution of Professional Civil Servants has been urging for some time that members of the scientific staff of a department are as likely to make as good administrators as the men with no knowledge of the affairs of the department at present chosen. From the above Act, it appears that this is recognised in the United States, and in their civil service, professional and scientific work is administered by men with professional and scientific experience. The salary attached to the highest posts, whether professional or administrative, is 7500 dollars per annum.

A SMALL but instructive pamphlet on the co-operative development of Australia's natural resources has been published by the Commonwealth Institute of Science and Industry. The whole field of Australia's resources is briefly surveyed and attention is directed to certain urgent problems that await solution. Particularly important is the section dealing with agricultural and pastoral problems. The ravages of vegetable and animal pests are shown to be enormous. In New South Wales and Queensland alone, the total area covered by the prickly pear is not far from double the entire cultivated area of the Commonwealth. From plant diseases alone the annual loss to Australia is estimated at more than 5,000,000*l.*; animal pests are even more costly. In a bad year the sheep-fly may cause a loss of 4,000,000*l.* A long list is given of investigations needed in the interests of agricultural, pastoral, and forest industries. The pamphlet makes a strong plea for the application of scientific method and research in the development of Australia's resources. Copies may be had free of charge on application to the Director of the Institute at Melbourne.

AMONG the many new periodicals of varying aims and quality relating to wireless telegraphy and telephony, we are glad to welcome a new-comer in *Experimental Wireless*, of which the first monthly

issue is before us. This in its own words is a "Journal of Radio Research and Progress," and wisely leaving to the more popular type of paper, elementary matter, broadcasting news, and doings of societies, concentrates upon articles on recent developments and experimental research. For example, a new connexion for valve generators, in which the oscillating circuit is connected between the grid and the filament, is described in an article by E. W. Gill, and the possibilities of the neon tube both as an oscillator and a receiver are discussed by E. H. Robinson. Another suggestive article deals with the correction of distortion produced by amplification, especially in the case of loud speakers. Notable among several other important contributions is an account of investigations of the Radio Research Board on the fading of signals. Another way in which the proprietors of the journal are encouraging research work is in the maintenance of a laboratory and testing service whereby readers' apparatus can be calibrated and other electrical measurements made entirely free of charge. The journal should be an important help to workers in wireless and is entirely independent of trade interests or other wireless organisations.

DR. A. KOSSEL, the well-known physiological chemist of the University of Heidelberg, celebrated his seventieth birthday on September 16 last.

THE Fothergillian gold medal and prize of the Medical Society of London have been presented to Sir Arthur Keith, Conservator of the Museum of the Royal College of Surgeons.

THE Thomas Hawksley lecture of the Institution of Mechanical Engineers will be delivered at the institution on Friday, November 2, at 6 o'clock, by Sir Westcott S. Abell. The subject will be "The Mechanical Problems of the Safety of Life at Sea."

WE much regret to announce the death on October 10 of Dr. J. A. Harker, F.R.S., at the age of fifty-three; of Dr. A. A. Rambaut, F.R.S., Radcliffe Observer, Oxford, and late Royal Astronomer of Ireland, on October 14, at the age of sixty-four; and of the Hon. Nathaniel Charles Rothschild, on October 12, aged forty-six.

THE Council of the National Institute of Agricultural Botany has appointed Mr. A. Eastham to be Chief Officer of the Official Seed Testing Station for England and Wales. Mr. Eastham, who studied agriculture and botany at the Lancashire Agricultural School, Cheshire Agricultural College, and the University of Edinburgh, completed his training in Canada, where he specialised in agricultural botany. Previous to his return to England, Mr. Eastham held botanical and seed-testing appointments in Canada.

PROF. W. D. TREADWELL, of the Technical High School, Zürich, will lecture on "Electrometric Methods in Analytical Chemistry" on November 2, under the auspices of the Manchester sections of the Society of Chemical Industry, the Institute of Chemistry, the Society of Dyers and Colourists, and the Manchester Literary and Philosophical Society.

THE fifth of the series of public lectures on "Physics in Industry," being given under the auspices of the Institute of Physics, will deal with the subject of "Physics in the Textile Industries." It will be delivered by Dr. A. E. Oxley, physicist to the British Cotton Industries Research Association, at the Institution of Electrical Engineers, Victoria Embankment, London, on Monday, October 22, at 5.30 P.M.

THE sixth annual general meeting of the British Association of Chemists will be held at the Chemical Department, University of Birmingham, Bournbrook, on Saturday, October 27. A chemical exhibit has been arranged by Prof. G. T. Morgan, to precede the meeting. The Society's annual dinner will be held at the Queen's Hotel, Birmingham, during the evening. The president, Dr. H. Levinstein, will take the chair at both the general meeting and the dinner.

ACCORDING to a Press announcement, a "Mammoth's Shoulder Blade" has recently been landed at Douglas, Isle of Man, having been brought up in a trawl off Ramsey. The bone is supposed to be the shoulder blade of a mammoth. From the back to the end of the blade is 6 ft.; the bone is 2 ft. thick and more than 3 ft. wide. Lengthy accounts were given of the mammoth, the period in which it lived, etc. Photographs have been submitted to Mr. T. Sheppard, of the Municipal Museum, Hull, from which it is clear, as might have been expected, that the "bone" was the skull of a whale.

RECENT issues of the *Times* (September 29 and October 10) reproduce many interesting photographs of the effects of the great earthquake in Japan. They show how well some of the great public buildings in Tokyo (such as the Metropolitan Police Station and the Imperial Theatre) withstood the shock of the earthquake, though they were afterwards destroyed by fire. The magnitude of the sea-waves is represented by a photograph of a scow, or flat-bottomed ferry-boat, thrown bodily on to the quay at Yokohama. A third picture illustrates a not uncommon effect of great earthquakes, that of railway-lines left suspended in air while the bridge below has collapsed.

A GRANT of 25,000*l*. has been made by the Development Commission to the new Research Institute for the investigation of animal diseases to be erected in connexion with the Royal Veterinary College, Camden Town, London. Sir John McFadyean, principal of the College, will be the first director of the Institute.

THE report of the field work of the Smithsonian Institution for the past year describes the manifold activities of this important body. Accounts are given of no less than twenty-two expeditions organised by it and its branches; they include geological explorations in the Canadian Rockies: the use of the great 100-inch telescope at Mount Wilson Observatory in connexion with a special vacuum bolometer and galvanometer to measure the heat in the spectrum of the brighter stars: an expedition to the North Pacific Fur Seal Islands: the collection of Australian fauna for the Museum, and a similar enterprise in little-known parts of China: botanical investigation in the

Republic of Salvador and Guatemala: archæological studies at the Mesa Verde National Park, Colorado, and of totem poles in Alaska. Less generously endowed scientific institutions in Great Britain will look with envy on such enterprises, but will recognise them with full appreciation as important additions to the general stock of human knowledge.

THE Rede lecture for 1923, by Prof. H. A. Lorentz, on "Clerk Maxwell's Electromagnetic Theory" is to be issued in pamphlet form in November by the Cambridge University Press.

MESSRS. DULAU AND Co., LTD., 34 Margaret Street, W.1, have just circulated a useful catalogue (No. 105) of second-hand books on entomology, general zoology, geology, and mining. Nearly 2000 works are listed, and the prices asked appear very reasonable.

MESSRS. ERNEST BENN have in their autumn list several books of scientific interest, among which we notice "The Principles and Practice of Wireless Transmission," by Parr, in which the theory of the production and control of wireless waves is set forth in non-technical language; "Across the Great Craterland to the Congo," by A. Barns; "The Diseases of Glasshouse Plants," by Dr. W. F. Bewley, of the Cheshunt Experimental Station, giving the practical results of the experimental work of the station in recent years; "Successful Spraying," by P. J. Fryer, which is primarily intended as a handbook for the practical grower wishing to know the results of recent researches upon the subject; "An Introduction to the Study of Chinese Sculpture," by L. Ashton, which professes to be the first European book dealing with this branch of Chinese art; and "Plastic Art in China," by O. Siren, with an introduction and epigraphic notes by P. Pelliot.

PROF. W. E. DALBY is bringing out, through Messrs. Edward Arnold and Co., "Strength and Structure of Steel and other Metals," the main purpose of which is to correlate strength of metals with their structure. In this volume the subject has been considered from the point of view of the engineer, and, so far as possible, in terms readily understood by the engineer. Other books in the same publishers' announcement list are: "A Handbook of the Coniferæ and Ginkgoaceæ," by W. Dallimore and A. B. Jackson, containing descriptions in easily understood terms of all the cone-bearing trees, with information upon their economic uses and cultivation. Although the book is primarily a general work upon conifers, special attention has been given to those that are hardy in the British Isles or are of outstanding economic importance. A feature of the work is the series of keys to genera and species which are designed to assist beginners in the work of identification. "British Hymenoptera," by A. S. Buckhurst, L. N. Staniland, and G. B. Watson, with an introduction by Prof. H. Maxwell Lefroy, being an introduction to the study of the habits and life-histories of British saw-flies, wood-wasps, gall-flies, ichneumon-flies, ruby-wasps, digger-wasps, mud-wasps, wasps, bees, and ants. Information is given as to their identification, and technical terms are carefully explained.

Our Astronomical Column.

THE WANT OF SYMMETRY IN STELLAR VELOCITIES.—Proc. Nat. Acad. of Sciences, U.S.A., for September contains an article by Dr. G. Strömberg, of Mt. Wilson, on this subject. This unsymmetrical distribution was first found by B. Boss from a study of measures of parallax and radial velocities; later Adams and Joy found it independently. Stars of high speed appear to move towards the hemisphere between galactic longitudes 160° and 340° (through 250°).

Dr. Strömberg extends the research to the globular clusters and spiral nebulæ, finding that all known objects appear to show the same asymmetry; he conjectures that it may arise from the existence of a fundamental system of reference, with regard to which excessive velocities are very infrequent. The stars of moderate velocity were found to be divisible into two groups, one with a slightly eccentric velocity-ellipse in the galactic plane, the other with a more eccentric ellipse.

The stars of high velocity give an ellipse with axes parallel to the last ellipse, while the globular clusters and spiral nebulæ give circular distribution: in each case the group-motion increases *pari passu* with the internal motions. On the assumption that the spiral nebulæ have acquired the maximum attainable velocity, he calculates the position of the fundamental frame, and shows that referred to it the sun is moving with velocity 651 km./sec. towards R.A. 305°, N. Decl. 75°.

NEW TRANSIT INSTRUMENT AT PARIS.—M. B. Baillaud, director of the Paris Observatory, describes in the *Comptes rendus* of the Paris Academy of Sciences for August 7, a new transit instrument which has been erected at the Observatory for the determination of the time that is distributed by wireless signals from the Eiffel Tower. These signals are now used so widely that the question of their degree of accuracy is important to many astronomers; hence an instrument was designed of such a size that it could be reversed on every star. The object glass is by M. Viennet, and is of excellent quality; its aperture is 4 in. and focal length 48 in. The magnifying power is 60; the self-registering micrometer has two threads that travel in opposite directions at the same rate, crossing each other at the centre of the field. The threads are driven by electric motor and the rate of driving is regulated by a rheostat. The object of the two threads is to save the time required to get the star on the thread again after reversal; having been observed on one thread up to reversal, it is automatically found very close to the other after reversal. The order of positions is reversed for alternate stars.

The level error is found both by spirit levels and by nadir observations. The collimation error is at present determined on the nadir, but collimators are in course of erection.

The results of time determination are satisfactory. The figures that are printed never show a greater range for separate stars on the same night than a tenth of a second; it seldom exceeds half of this amount.

Research Items.

The Sheel-na-gig at Oaksey.—The Sheel-na-gig or phallic figure, usually found in churches, is probably the survival of a fertility cult. That at Oaksey, in North Wiltshire, is described in the September issue of *Man* by Miss M. A. Murray and Mr. A. D. Passmore. It is carved out of the same stone as that of the church, a thirteenth-century edifice, but there is nothing to show whether it is in its original position, or whether it is contemporary with, or earlier than, the church. But the size and importance of the left hand in the sculpture are noteworthy and suggest a pre-Christian origin for the figure. The flat surface of the stone has been slightly hollowed so as to make the figure stand out in relief. The weathering of the stone has practically destroyed the features, which appear to have been rudely indicated.

The Island Culture Area in America.—In the thirty-fourth annual report of the Bureau of American Ethnology, 1912–13, recently issued, Mr. J. Walter Fewkes discusses the prehistoric island culture area of America. He concludes that, from the data now in hand, it is possible to distinguish three cultural epochs in the West Indies. The earliest people were cave-dwellers, a mode of life that had not totally disappeared at the arrival of Columbus, a culture extending through both the Greater and Lesser Antilles, though, owing to the absence of caves, it naturally did not exist in the Bahamas. The absence of fine stone objects separates the West Indian cave-man from that of the following epoch, the agricultural West Indian, when stonework reached a perfection not excelled elsewhere in the two Americas. The archæological evidence of the third epoch, or that of the mixed race formed by an amalgamation of agricultural and Carib elements, appears to indicate a decline in the arts, as would naturally be expected from the nature of the life of the inhabitants. All three stages of culture—cave-man, Tainan, and Carib—coexisted when the West Indies were discovered. The first mentioned had been driven to isolated, undesirable localities; the Tainan held the Greater Antilles, but had been submerged in the Lesser except in Trinidad; the Carib occupied the islands between Trinidad and Porto Rico, and was slowly encroaching on the Greater Antilles at the coming of Columbus.

Early Arithmetical Processes.—At the recent meeting of the British Association, the Rev. C. A. Brodie-Brockwell, professor of Hebrew and Semitic languages, law, and history in McGill University, Montreal, presented to the Anthropological Section a paper dealing with the evolution of arithmetic with special reference to the principles of compound-time or reckoning. He maintained that modern scholars, through neglecting to take into account the fact that pre-Christian Mediterraneans used arithmetical processes without analogy in modern arithmetic, had obscured the meaning of ancient time determinations. He proceeded to show wherein the ancient processes differed from the modern, and suggested that owing to the fact that the ancients worked in units larger than those we employ, it was necessary to divide or subdivide according to the method of computation before the figures were comparable with modern calculations. Thus, according to the method of computation, any given figure may be divisible by two, three, or four to arrive at its modern equivalent. Prof. Brockwell concluded by demonstrating the application of his theory of compound-time to a Babylonian tablet, previously undeciphered, which was discovered by Prof. Hilprecht, to Plato's Millennium Cycle, and to Proclus' Pythmenic Indices.

Imagery in Thinking.—In *Discovery* for August, Prof. T. H. Pear gives a very lucid account of the vehicles and routes of thought. He thinks that the recent mobilisation of psychologists for practical work has led to the neglect of a problem which at first sight appears rather theoretical, but may actually have far-reaching practical results. It is well known that people vary in the way in which they think, but having classified people as visuals or audiles, there is a tendency to neglect the consequences. The writer thinks that for practical purposes people can be described as visualisers or verbalisers according as they tend to think in pictures or words. Each type of thinking has its own advantages and also its own drawbacks, and extremes of either type often fail to understand the other, not infrequently with serious consequences. Should a teacher or a doctor be too exclusively one type it might account for some failures in dealing with particular pupils or patients. The visualiser he holds is less likely to be impressed by an orator's rumbling stream of words or less easily hypnotised by a sonorous phrase or platitude, but, as against this, he may be paralysed by impressive tailoring or a pretty smile. The article is an excellent example of sound scientific thought expressed in non-technical language.

Sex Reversal in the Common Fowl.—At the recent meeting of the British Association in Liverpool, no little interest was excited by Dr. F. A. E. Crew's account of a case of complete sex-reversal in the common fowl. A hen, after laying a number of fertile eggs in a perfectly normal manner, was converted into a cock which became the father of chicks. This remarkable reversal of sex seems to have resulted from the destruction of the ovary by tubercular disease and its replacement by testes. Dr. Crew has published his observations on this and similar cases in a recent number of the Proceedings of the Royal Society (Series B, Vol. 95, No. 667) and Miss Honor B. Fell gives a more detailed account of their histological features in the first number of the *British Journal of Experimental Biology* (October).

Reproduction in *Paludestrina jenkinsi*.—It has long been suspected that the Gasteropod mollusc, *Paludestrina jenkinsi*, reproduces itself by means of parthenogenetic ova. If so, it is the only mollusc in which this phenomenon is known to occur. The probability is converted into a practical certainty by the careful breeding experiments of Mr. Guy C. Robson, described in the first number of the *British Journal of Experimental Biology* (October). No male has ever been observed and there is no evidence of hermaphroditism. This little snail is also remarkable for the curious manner in which, in the British Isles at any rate, it has extended its range in recent years from brackish estuaries to inland fresh waters, which, as Mr. Robson suggests, may have something to do with its parthenogenetic habits.

The Shape of Plant Cells.—The botanist who is under the impression that the typical shape and mode of division of a normal parenchymatous cell is fully represented by the usual text-book diagram, where such cells are always in transverse or longitudinal section, is recommended to study the paper by Mr. Frederic T. Lewis in the Proceedings of the American Academy of Arts and Sciences, Vol. 58, No. 15. The author has prepared serial microtome sections of the pith of the elder, from which outline drawings and then wax models of the cells have been prepared by standard methods. The result is to show that the cells are essentially tetrakaidecahedra,

as the mathematicians and physicists had anticipated; from the models it is possible to reconstruct the method by which this form is restored after cell division.

"Red Plant" in Strawberries.—During recent years the spread of a mysterious disease among strawberries has been reported under this name from one centre of strawberry growing after another, in some districts the strawberry growing industry being seriously threatened by its depredations. Typically diseased plants have been under observation at the Research Station, Long Ashton, Bristol, and now Messrs. E. Ballard and G. S. Peren report that the disease is only a special form of the well-known "cauliflower" disease of strawberries which has been known for some thirty years and was first discovered by Mrs. Ormerod. As in the case of the "cauliflower" disease, the causal organism in "red plant" is found to be the eelworm *Aphelenchus fragariæ* Ritz. Bos, a conclusion which, as recent correspondence in the *Gardeners' Chronicle* witnesses, is in agreement with that of other practical observers familiar with the disease. "Red plant" appears to be an unfortunate name for the disease, as it is only when the eelworm attack synchronises with a certain stage of development in some varieties of strawberry that the striking red colour develops in the petiole and lamina of the ill-developed leaves.

Control of Finger-and-toe by Liming.—In Bull. No. 29 of the North of Scotland College of Agriculture, Prof. Hendrick describes an experiment carried on for several years at Craibstone under conditions particularly conducive to the spread of finger-and-toe disease. The soil is sour and very poor in quality, and turnips have been grown on the same land since 1915; mass infection has been induced by leaving plenty of diseased material upon the plots, and manures favourable to the increase of the disease have been systematically applied. Although disease occurs yearly on the limed plots as well as on the unlimed, in the former case a large proportion of the roots are fit for use, even though touched by disease, whereas in the latter case most of the roots are rotten and unusable. It would seem that though a cure is not effected, some measure of control can be exercised by adequate applications of lime, in moderate excess, but in each individual case it will be necessary to balance the cost of the liming against the improved value of the crop, in order to determine whether the procedure is economic and advisable.

Inaudible Air-waves.—The current number of *Science Progress* (pp. 294-297) contains an article by Dr. C. Davison on inaudible air-waves resulting from explosions. These waves are manifested chiefly by the rattling of windows, the disturbance of pheasants, and the traces of barographs. Such effects are noticed far beyond the area within which the sound of the explosion is audible. For example, the firing during the Dogger Bank action of January 24, 1915, was heard in England to a distance of 208 miles, while pheasants were disturbed near Workington (320 miles). The velocity of the inaudible air-waves is slightly less than that of sound, but, when a silent zone is developed, the sound-waves, which at first outrun the inaudible waves, in the outer sound-area follow them after a brief interval. As windows are shaken and pheasants are disturbed in the silent zone, it is suggested that the inaudible air-waves cross the silent zone close to the ground while the sound-waves travel at a somewhat greater elevation.

Industrial Water Supply in the United States.—An inquiry into the nature and source of the water used in industrial establishments in the United States has led to some interesting results. These are published in Water Supply Paper No. 496 of the United States Geological Survey. The census of 1920 showed that 35·7 per cent. of the total population lived in 287 places each of more than 25,000 inhabitants. Analyses of the water supply of these 287 places and, in addition, of many smaller places, are given so that each state is represented by at least two cities. These details deal with the bulk of the water used for industrial purposes even if they show the character of the water used by less than half the total population. Many of the analyses are the work of the Geological Survey; others have been obtained from municipal, state, waterworks, and commercial laboratories. Of the 307 cities quoted in the report the great majority has surface water but a few have ground water. A sketch map shows the average distribution of hardness. This quality, due to calcium and magnesium salts, is practically the only one of much industrial importance. The figures show that of the 39,000,000 persons served with the waters analysed, about 17,000,000 use water with less than 55 parts per million of hardness, 6,000,000 use water with 55 to 100 parts per million, and most of the remainder use water with 100 to 200 parts of hardness per million. The pamphlet contains also a discussion of the treatment of water for public supplies.

The Determination of Sea-level.—In an article in *Science Progress* for October on the levels of land and sea, Sir Charles Close discusses the problem of arriving at the mean level of the sea as the datum to which height on the Ordnance Survey maps of Great Britain are referred. What is required is the mean position of the sea surface as determined over a considerable period of time, at all states of the tide, and not merely at high and low water. The most satisfactory way of arriving at this mean is by the use of self-recording tide-gauges. In practice the mean of the hourly tides measured over a long period will give the result desired. For this purpose tidal stations were set up at Dunbar in 1913, Newlyn in 1915, and Felixstowe in 1917, and are still at work. Each of the two stations of longest duration show a range in height of the annual mean sea-level of 2·3 inches. Hence it is obvious that the value of mean sea-level cannot be obtained during the period of a year. At other stations in the British Isles and elsewhere, annual fluctuations have been noted. In fact the probable variation of height of any one year from the mean of a large number of years is about half an inch. The most important variations are meteorological and are in part local, in part world-wide. Of smaller significance are the latitude variation tide with a period of 431 days and the lunar tides of 18·6 years.

Sunspots and Air Temperature in America.—The *Monthly Weather Review* for May contains an article on sunspots and terrestrial temperature in the United States based upon a communication to the American Meteorological Society by Mr. A. J. Henry of the U.S. Weather Bureau. It is pointed out that annual deviations of temperature give evidence of short period variations within the 11-year sunspot cycle. Sometimes warm and cold years alternate; in other cases the cycle, cold to warm, would be completed in three, four, or five years. During the period 1870–1921, a heat maximum corresponds fairly well with a maximum of sunspots and *vice versa*. Prior to that period the agreement is not so good. The author mentions that until some allowance can be satisfactorily made for the movement of cyclones and anticyclones, it is hopeless to seek for effects of changes

in the intensity of solar radiation in the temperate zone. Observations are used for as many stations as practicable in the United States, and in using the published means of temperature derived from the daily extremes, appropriate corrections have been applied to reduce to true means. Temperatures dealt with range between the years 1750 and 1921, but the number of stations are very few prior to 1825. Summarising the conclusions and results of various authorities on the subject, the author states that it appears that the weight of evidence is in favour of the existence of a variation in the air temperature of the globe corresponding roughly with that of the spottedness of the sun, an increase in spots corresponding with diminished terrestrial temperature and *vice versa*. The effect is best shown in the tropics and is difficult to trace in temperate latitudes. There were three pronounced maxima and minima of temperature between 1873 and 1921, the maxima occurring in 1878, 1900, and 1921, and minima in 1875, 1893, and 1917.

BOMBAY MAGNETIC CURVES.—We have received from the Director of the Government Observatory, Bombay, a collection of photographic copies of Bombay magnetic curves for selected disturbed days during the years 1906 to 1915. Records are included from several hundred days, covering about 150 large sheets. Magnetic disturbance at Bombay is seldom large except in H, the intensity of the horizontal component. The curves reproduced are mostly for this element, but the declination and vertical force curves are also reproduced for some of the storms. The times, and the base line and scale values, are clearly shown in every case, and the reproductions are excellent; thus much valuable information is deducible as to the character of magnetic disturbance in Bombay. As compared with curves from European or North American stations, the Bombay curves are comparatively free from rapid oscillations. Some of the curves, however, are decidedly lively, including those for February 9-10, 1907, September 12-13, 1908, May 14-15, 1909, September 25, 1909 (when there was considerable loss of trace), and June 17, 1915. There are many examples of "sudden commencements" of magnetic storms, all or nearly all exhibiting the characteristic rapid rise of horizontal force. In some cases this increase of force persists for a number of hours, the curve having a crested appearance; in other cases a fall to less than the normal value follows hard on the initial rise. The weight of the volumes of collected curves is considerable, and the Director of Bombay Observatory expresses his regret that owing to the heavy postage, and the necessity for economy, he has been obliged to restrict the issue. He would be glad, however, on receipt of the postage, to send a copy to any magnetician who would like to have one.

COCONUT OIL.—The coconut oil industry is surveyed in the *Chemical Trade Journal* for September 7. This substance is known to us as a fat; only in warmer climates is it an oil. It is obtained from the kernels of the fruit of the coconut palm, which flourishes in India, Ceylon, and other tropical countries. The first importations into Europe occurred in 1815; they have since steadily increased. The article contains brief accounts of the properties (physical constants, etc.), composition, and manufacture of the oil. The bulk of the oil is used in the soap and candle industry. Future prospects are discussed.

A DIRECT READING X-RAY SPECTROMETER.—In 1915 Duane and Hunt found that a spectrum of general X-rays is terminated sharply at the short wave end, the boundary wave-length being precisely connected by Planck's quantum relation with the maximum voltage applied to the X-ray bulb. The output of general X-rays is roughly proportional to the square of the voltage, and provided the peak-voltage is the same, the energy-distribution curve of the X-ray spectrum is found not to vary markedly with the shape of the wave-form of the exciting potentials which obtain in practice, whether from coil or transformer. For medical purposes, at any rate, it is sufficient to assume that in the absence of a filter the general quality of the rays is independent of the means by which the X-rays are generated but is determined only by the position of the quantum limit. Drs. Staunig, March, and Fritz, of Innsbruck, have designed a convenient type of X-ray spectrometer for measuring this boundary wave-length. In this instrument (the English agents for which are Messrs. Schall and Son, 71 New Cavendish Street, W.1) a narrow slit of X-rays passes through a thin plate of rock salt crystal and the deviated beam is observed visually as a narrow band on a fluorescent screen provided with a scale of wave-lengths. The crystal is capable of rotation, and the observations consist essentially in measuring the minimum deviation between the reflected beam and the undeflected beam. In practice it is convenient to ascertain both the right-hand and left-hand positions of the deflected beam and halve their angular separation, thus avoiding a determination of the zero position. It is important that the observations should be made in a darkened room by an eye thoroughly adapted to darkness. The spectrometer, which should be earthed, is brought as near the X-ray tube as possible, the protection for the operator being afforded by sheet lead. As will be gathered, the instrument is also capable of being used as a means of measuring peak-voltage.

TEMPERATURE OF THE CROOKES DARK SPACE IN GLOW DISCHARGE.—Herr R. Seeliger, in the issue of the *Zeitschrift für Physik* of June 29, contests the opinion recently expressed by Günther-Schulze that the temperature in the dark space of the glow discharge is high (NATURE, October 13, p. 557). The canal ray particles are in part neutral, and do not behave like elastic spheres to which the geometrical laws of mechanical collision can be applied. When collisions take place in which the charge is altered, the changes of velocity and of direction are small; when the colliding particles are absorbed, this takes place without previous appreciable loss of velocity. It is only for the first type of collision that the free path is of the same order as the molecular free path; for the second it is very much greater. For ionic velocities, with high or "anomalous" cathode drop, these properties of the canal rays can probably be directly applied to the glow discharge; for smaller values, corresponding to normal cathode drop, similar complete observational results are not available. Certain qualitative observations (*e.g.* those of Dempster) point to the fact that things are essentially the same in both cases; and observations made so far on canal rays (+ions) do not suggest the existence of the difficulties raised by Günther-Schulze; but seem rather to be in agreement with the results obtained by him as to energy relations and distribution of velocity, without assuming a high temperature in the dark space. All direct measurements of the temperatures of the cathode, and of the dark space, have shown that these are only a little higher than that of the surroundings, not much more than 100° C., although in special cases the temperature of the cathode can be raised to the melting, or even the vaporisation, point.

A Library List of Scientific Books.

ABOUT two years ago the Washington Academy of Sciences published a list of one hundred popular books in science suitable for inclusion in public libraries. The list has since been revised, and is reprinted below. The original list included the titles of forty-three books by British authors, but many of these have now been omitted as the volumes are out of print. All the works in the present list are obtainable through booksellers in the usual way. As the list was compiled for American libraries, the majority of the books mentioned in it are by American authors. We know of no similar list for British libraries, but one would no doubt be welcomed by librarians and others. Though librarians may be able to discover which books are interesting, they have no easy way of finding out which of such books are trustworthy and which are not merely unorthodox but misleading or misinforming.

In inviting correspondents to assist in preparing the list subjoined, the Committee of the Washington Academy of Sciences asked that the tests to be applied in selection of books should be as follows: "(1) The book must be *readable*; if the average visitor to the library takes the book home, it will interest him so much that he will read it through, and will come back to ask the librarian for another on the same subject. (2) It must be *accurate*; preferably written by one who knows his subject at first hand. Minor points are: (3) up-to-dateness; (4) small bulk; (5) attractive binding, type, and illustrations.

"The relative number of books in different branches of science is not fixed. For example, a good book in mathematics may be substituted for a poor book in anthropology, provided anthropology is not thereby left wholly unrepresented."

The Committee has performed a useful service in selecting one hundred books which it feels fairly sure are scientifically trustworthy, and believes to be readable. It is obvious that a list of this kind must be subject to revision, and indeed should be revised frequently to keep up with the progress of science and the publication of books better adapted to the purpose. The Committee adds: "In general, it need hardly be said that even a tried and tested list can never be completely satisfactory, for the simple reason that there is no such person as the 'average reader.' Every individual has his own foundation of natural capacity and education, and his own background of experience and interests. We therefore need one series of lists covering all types of capacity, another series differentiated according to kind and duration of education, another series distributed according to age and to variety of experience, and still another adapted to the varied types of man's interests. Provided with such a set of lists we could name twenty-five scientific books which would be almost certain to interest keenly any given individual. Lacking such provision, we can only hope, on behalf of the very general list herewith submitted, that every reader who can be induced to read anything at all serious will find on the list a few books which appeal to him strongly, and that none of the other books will give him the impression that science makes reading-matter which is difficult or forbidding."

The Zermatt Meeting of the Swiss Society of Natural Science.

The 104th meeting of the Helvetic Society of Natural Science was held at Zermatt on August 30–September 2. On the evening of the first day, after a business meeting in which Lucerne was chosen as the meeting-place for next year, the Society was welcomed by the local and cantonal authorities at a soirée given by the Science Society of the Rhone Valley, called the Murithienne. The next day, which was very wet, was devoted appropriately to business: general meeting with speeches in the morning; sectional meetings in the afternoon.

M. le Chanoine Besse, curé of Riddes, who had been chosen as annual president, took the opportunity of his opening address piously to recall the names and the lifework of some of the most prominent *savants* of the valley. A member himself of the Congregation of St. Bernard, he was able to point to the long tale of patient study pursued by successive members of the same body; in particular he sketched the life of Laurent-Joseph Murith, 1742–1816, geologist, conchologist, ornithologist, entomologist, as well as archæologist, who lived just long enough to be one of the first members of the infant Helvetic Society. Among the other men whose lives he told in impressively simple language I would only mention that of Walther Ritz, 1878–1909, the brilliant young

physicist, born at Sion, whose ideas not only made a great stir at the time, but have also proved a source of inspiration since.

In the various Sections a number of interesting communications were made. The Mathematical Section opened with a causerie of my own on the nuptial number of Plato. Prof. Speiser then explained a very pretty geometrical figure of rational points on the straight line and circles touching the latter in those points and touching one another, and Prof. Wavre, of Geneva, gave a short account of some work on a substitution in the realm of several complex variables. After the meeting I communicated by desire a new theorem of Prof. W. H. Young's in the theory of trigonometric series; he had promised to speak on this subject, but was prevented from attending the meeting. I pointed out how the theorem itself as well as the proof again illustrate the efficacy of the method of integration with respect to a function of bounded variation.

In the Physical Section the communications fell distinctly into two classes, pure and applied, the latter being in the majority. The former included an account of the separation of neighbouring radioactive substances as carried out in the Brussels laboratory of August Piccard, and another of experiments made in Prof. Perrier's laboratory at Lausanne by S. Gagnebin, on the thermic variation of the dielectric constants of quartz. These latter form part of a general scheme of research undertaken in the Lausanne laboratory on the dissymmetries of solid matter; they constitute, moreover, a fine example of the use of the triode lamp in the problem of measuring exceedingly feeble capacities with imperfect isolation. In applied physics we may in particular mention an account of the determinations of the variation of the first modulus of the elasticity of steel under changes of temperature, made in Prof. Jaquerod's new horological laboratory at Neuchâtel; it is expected that the result of the creation of this department will have a beneficial effect on the Swiss watchmaking industry. Almost all the remaining contributions consisted of technical improvements in telegraphy and wireless telephony, among which we note the realisation of very simple and strong, but small, apparatus, of national importance to Switzerland in so far as they are to be set up in the huts of the Alpine Club.

The Botanical Section was strongly represented. P. Konrad gave an account of his researches on certain fungi in the Jura; in particular he has found a new type of Hymenomycetes which enables him to settle certain systematic questions hitherto unsolved. Prof. Schinz, of Zürich, showed a collection made by one of his staff, Prof. A. Thelling, unfortunately himself absent, of the flowers of Zermatt, corroborating, among other things, the known fact that, in this region, plants are able to exist at a greater height than in other parts of Switzerland.

Dr. W. Vischer, of Bâle, spoke upon heredity in relation to the physiological properties of *Hevea Brasiliensis*, the chief rubber producing plant at the present time. Prof. E. Fischer, of Berne, gave two communications; the first on the work carried out under his direction by Dr. Baumgartner, who has been able to show that an interesting family of fungi, the Laboulbeniaces, hitherto supposed to be confined almost exclusively to North America, contains numerous representatives in Switzerland. The excessive minuteness of these organisms renders their recognition extraordinarily difficult. The second of Prof. Fischer's communications related to the infection of certain plants by rust-fungi (Uredineæ), which he had collected in the Rhone valley, and by means of which new light is thrown on the susceptibility of determinate races or groups of plants to infection by definite fungi. Prof. Jäggli gave great pleasure to his audience by his account in Italian of the mosses he has studied in the pass of Sasso Corbaro, near Bellinzona; he has found several hitherto unknown in the Tessin. The remarkable variety found in such a small area is doubtless due to the lie of the region in relation both to the Alps and the Mediterranean. Fernand Chodat, the son of Prof. Chodat, of Geneva, spoke upon the determination of the concentration of hydrogen ions in the soil and its influence on the vegetation. In places where the same group of plants occurs, the concentration is found to be remarkably constant in spite of external differences of the surroundings; hence it may be expected that this factor plays an important part in the distribution of plants. Prof. Schellenberg, of Zurich, spoke upon a subject closely connected with that of Prof. Fischer's second communication. The parasitic fungus which formed the subject of his investigations, Sclerotinia, attacks especially the quince tree, and others of the same family.

In the Section of Geophysics, Meteorology, and Astronomy, we may refer to an interesting communication by O. Lütschg, of Bern, giving exact details with respect to the advance of a certain glacier founded on archives of the year 1300; and in the Section of Anthropology and Ethnology, in addition to the account given by Prof. Pittard, of Geneva, on Palæolithic traces in Northern Africa, we must notice H. Junod's communication on totemism among the Tongas, Pédis, and Vendas. The curious customs which he had chronicled during his long residence in South Africa among these peoples seem to indicate that the totemism which exists, more particularly among the Pédis, may be a relic of the past, the real meaning of which has been lost and the practice become degenerate.

Among other communications of interest we note, in the Section of the History of Medicine and of Science, Dr. Morgenthaler's account of a hysterical case at the beginning of the sixteenth century. The account as written down by the doctors at the time is so exact that it is possible in the present day to diagnose the case precisely. In those days the patient was fortunate to escape being tried and burned for witchcraft. In the same Section, Prof. G. Senn examined carefully the pharmaceutical-botanical handbook of Theophrastus (chapters 8-20 of his "Historia plantarum"), and came to the conclusion that we have here a conglomerate of results from various sources, which were edited rather inefficiently at a later date by an unknown person. Nevertheless, the book has scientific value, and certainly contains parts due to Theophrastus.

In each of the Sections there was, besides the scientific communications read and discussed, a business meeting which, for the most part, presents no interest to a British public; we notice, however, with pleasure that Sir Clifford Allbutt was elected an honorary member of the Society, in recognition of his important contributions to the history of medicine. In the Physical Section, moreover, two matters of general interest came up: first, the question of the federation of the Swiss Physical Society with the International Union of Pure and Applied Physics, and secondly, the creation of a Swiss periodical for physicists. The Helvetic Society as a whole had already given in its adhesion to the International Research Council, and the question was put by the central president to the Physical Society, as a branch of the larger body. It was decided to answer in the affirmative. A Swiss Committee of Physics was there and then constituted, comprising

provisionally five Swiss members. This committee is to be considered as distinct from the committee of the Swiss Physical Society, which may contain non-Swiss members, and the possibility was left open of its being enlarged at a later date by the addition of electrical engineers, or representatives of other branches of applied physics. The committee will examine shortly the question of sending a delegation to the meeting which it is proposed to hold in December at Paris.

In discussing the second matter, it was pointed out that there does not exist at the moment any Swiss periodical devoted exclusively to physics, and in which memoirs in any one of the three national languages equally are accepted. The consequence is that much of the good work done in Swiss institutions is regarded outside Switzerland as belonging to the countries where the results are published. On the initiative of some of its members, the Society decided to consider at an early date the creation of a trilingual review, of the type of the *Helvetica Chimica Acta*, recently created for the purpose of publishing the work of Swiss chemists in Switzerland itself. The question is more difficult in the case of physics, since, unlike chemistry, it cannot count on the regular support of the industrial people. A committee *ad hoc* is to examine whether it will prove possible to transform and extend the *Archives des Sciences Physiques et Naturelles*, hitherto published at Geneva. This was the wish of Philippe Guye, and he had for years been working with this aim in view, when his untimely death deprived the world of science of one of its most valued leaders. It is to be hoped that the preparations which he had made will be found to render this transformation possible. The alternative would be to create a totally new review, the *Helvetica Physica Acta*.

GRACE CHISHOLM YOUNG.

University and Educational Intelligence.

BRISTOL.—Prof. J. W. McBain has received the degree of doctor of science from Brown University, Rhode Island, United States, where he is delivering a dedicatory address at the opening of the new chemical laboratories.

CAMBRIDGE.—Mr. H. Godwin, Clare College, has been appointed junior demonstrator in botany, and Mr. H. E. Green, Fitzwilliam Hall, re-appointed second assistant at the Observatory.

Dr. Mollison, Master of Clare College, has offered a gift of 500*l*. to found a prize to be called the "Mayhew Prize," to be awarded by the examiners in Part II. of the Mathematical Tripos to the candidate of the greatest merit, preferably in the subjects of applied mathematics.

LONDON.—Dr. A. Logan Turner will deliver the Semon lecture in the lecture hall of the Royal Society of Medicine, 1 Wimpole Street, W.1, on Thursday, November 1, at 5 o'clock, taking as his subject "The Advancement of Laryngology: a plea for adequate training and closer co-operative action." Admission will be free, without tickets.

A course of eight lectures on "Some Biochemical Aspects of Animal Development" is being delivered by Mr. H. G. Cannon in the Zoological Department of the Imperial College of Science and Technology on Mondays at 5.30, terminating on December 3.

SHEFFIELD.—The University Council has made the following appointments: Prof. F. C. Lea, to the chair of mechanical engineering, in succession to emeritus Prof. Ripper; Mr. R. R. S. Cox, to be assistant lecturer and tutor in mathematics; and Mr. M. H. Evans, to be an assistant lecturer in physics.

ACCORDING to the *Chemiker Zeitung*, Dr. James Franck has been appointed to the chair of physics in the University of Berlin, vacant by the death of Dr. Heinrich Rubens.

THREE residential scholarships for British women graduates, tenable at the American University Women's Club in Paris, have been awarded by the British Federation of University Women to the following candidates: Miss Olive Farmer (London and Cambridge)—Mary Ewart Travelling Scholar, 1923–24; Miss Benedicta J. H. Rowe (Oxford); and Miss Helen Waddell (Belfast)—Susette Taylor Fellow, 1923–24.

THE Department of Leather Industries of the University of Leeds has issued a report on the sessions 1921–23, in which it is noted that the Ph.D. degree of the university was conferred on completion of two years' research work in the department on Mr. E. C. Porter for a thesis on "The Alkaline Swelling of Hide Powder," while another former student of the department, Mr. F. L. Seymour-Jones, has been awarded a Ph.D. degree by Columbia University for a thesis on "The Hydrolysis of Collagen by Trypsin."

THE University of Leeds entertained on September 13 a party of members of the Institute of Journalists. In connexion with this visit a convenient summary of the history and activities of the University was printed, special prominence being given to the departments of Leather Industries, Colour Chemistry, and Textile Industries, all of which were inspected by the visitors. It is noted that to provide university instruction costs on an average 83*l*. a year for each full-time student, while the average fee paid by such students is 40*l*.

AN article on "The Civic University and the State" in the *Fortnightly Review* for October contains a timely plea for the recognition of the importance from an Imperial point of view of adequate provision in the English provincial universities for economic and industrial research and advanced studies in civics. Mr. MacInnes, the writer of the article, points out that were full advantage taken of the unique opportunities in the universities of Birmingham, Bristol, Leeds, Liverpool, Manchester, and Sheffield, for work in these fields they would attract from the Dominions many research students who would otherwise drift to foreign countries. Hitherto these universities have attracted very few of such students, owing partly to failure to make their resources sufficiently well known and to devise convenient procedures for students from abroad. Nor is this surprising. The university staffs are hard put to it to meet the requirements of English students, and in the absence of any special inducement to cater for the needs of students from abroad, it is not to be expected that they should go out of their way to do so. Something has been done by the Universities Bureau to disseminate in every part of the Empire a knowledge of the resources of the universities in other parts, but that is not enough by itself to stimulate intra-Imperial migration of students. Discussing the perils to which universities are exposed by reason of dependence on State subsidies, the article points out that a democratic community naturally inclines to the view that, since the people pay for their maintenance, as many persons as possible should enjoy their benefits, and as a large majority fail to appreciate the benefit of having in their midst a university pursuing, however efficiently, its traditional aims, they are inclined to look for benefits more direct and easily recognisable.

Societies and Academies.

MANCHESTER.

Literary and Philosophical Society, October 9.—H. B. **Dixon**: On coal-dust explosions at the Mines Department Experimental Station at Eskmeals. The coal-dust theory of explosions in mines, started fifty years ago, led to many small-scale experiments, both in England and abroad, which did not definitely solve the problem. The large-scale experiments instituted by the Mining Association in 1908 first showed the violence of pure coal-dust explosions and indicated methods to study and counteract them. In the model mine at Eskmeals, Cumberland, it has been possible to give complete demonstrations of the violent character of pure coal-dust explosions, and to obtain records of the speed and pressure of the flame. It has also made possible many experiments on the effect of damping the dust and of diluting it with inert shale or other incombustible powders. The Eskmeals Committee in 1914 advised a 1 : 1 mixture of coal and inert dust throughout the roadways of "dry and dusty" mines—as a minimum amount of inert dust. The experiments made this year with the finely ground dust from various coal seams in England and Scotland—especially that with the Arley Main dust—have shown that it is possible to explode a 1 : 1 mixture. But the precautions taken to meet the coal-dust danger have resulted in a great saving of human life. The yearly fatal accidents from explosions in mines during the decade 1873–1882 reached 661 per million workers, in the decade 1911–1920 the yearly average fell to 111; for the last three years the average has been still lower.

MELBOURNE.

Royal Society of Victoria, August 2.—Mr. Wisewould, president, in the chair.—C. **MacKenzie** and W. J. **Owen**: Studies on the comparative anatomy of the alimentary canal of Australian reptiles. The alimentary canals of lizards, skinks, monitors, and of poisonous and non-poisonous snakes, were described. Without a knowledge of the reptilian gastro-intestine there could not be a correct understanding of the apparent complex human intestinal arrangement and its method of fixation adapted to the erect posture. In the bearded and the frilled lizards, a well-defined cæcum appears together with development of mesenteric colon (human ascending colon). Associated with this is the presence of the mesial fold approximating the colon to the pyloric region, which is best demonstrated in Koala. Thus in these lizards is found early evidences of the method of accommodation of the large intestine to the erect posture.—G. G. **Heslop**: Further studies in contagious bovine pleuropneumonia.—E. W. **Skeats**: The evidence of Post-Lower Carboniferous plutonic and hypabyssal intrusions into the Grampian Sandstones of Western Victoria.—A. Jefferis **Turner**: New Australian Micro-Lepidoptera.—F. **Chapman** and C. J. **Gabriel**: A revision of the Australian Tertiary Patellidæ, Patelloidiidæ, Cocuclinidæ, and Fissurellidæ. The fissure, keyhole, and common limpets are discussed. Of the 23 species described, 14 are new. Three of the fossil species are still found living, and have an ancestry dating back three million years, the fossils being indistinguishable from those dredged up in Western Port Bay. The persistence of these species supports the idea of the general stability of the Australian continent since ancient geological time, so far as the absence of sudden changes of coast-line is concerned.

Diary of Societies.

MONDAY, OCTOBER 22.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. Shattock: Arteries.

INSTITUTE OF PHYSICS (at Institution of Electrical Engineers), at 5.30.—Dr. A. E. Oxley: The Physicist in the Textile Industries.

INSTITUTION OF MECHANICAL ENGINEERS (Graduates' Section), at 7.—J. Harrison: Four-wheeled Brakes for British Light Cars.

ROYAL SOCIETY OF MEDICINE (Odontology Section), at 8.—D. Caush: Presidential Address.

TUESDAY, OCTOBER 23.

ZOOLOGICAL SOCIETY OF LONDON, at 5.30.—The Secretary: Report on the Additions made to the Society's Menagerie during the months of June, July, August, and September 1923.—E. A. Spaul: Acceleration of Metamorphoses of Frog-Tadpoles by Injection of Anterior-lobe Pituitary gland Extract and Iodine.—H. C. Abraham: A New Spider of the Genus Liphistius from the Malay Peninsula, and some Observations on its Habits.—A. Subba Rau and P. H. Johnson: Observations on the Development of the Sympathetic Nervous System and Suprarenal Bodies in the Sparrow.—M. A. Smith: A Review of the Lizards of the Genus Tropidophorus on the Asiatic Mainland.—J. G. H Frew: The Larval Anatomy of the Gout-fly (*Chlorops taeniopus* Meig) and two Related Acalyptrate Muscids with Notes on their Winter Host-plants.—A. Loveridge: (1) Notes on Mammals collected in Tanganyika Territory, 1920–1923. (2) A List of the Lizards of British East Africa (Uganda, Kenya Colony, Tanganyika Territory, and Zanzibar), with Keys for the Diagnosis of the Species.

INSTITUTE OF MARINE ENGINEERS, INC., at 6.30.—W. S. Patterson: Boiler Corrosion.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Dr. G. H Rodman: A Talk about the Housefly and how it endangers the Health of Man.

ROYAL ANTHROPOLOGICAL INSTITUTE (at Royal Society), at 8.15—F. A. Mitchell-Hedges: The Discovery of an Unknown Race: The Culture of the Calchaqui of Central America.

WEDNESDAY, OCTOBER 24.

FEDERATION OF MEDICAL AND ALLIED SERVICES (at 12 Stratford Place), at 4.—Conference to consider what practical means, if any, are possible to extend the system of providing for the periodical medical examination of the Larger Assurance Policy Holders.

ROYAL MICROSCOPICAL SOCIETY (Industrial Applications Section), at 7.—J. E. Barnard: Lecture Demonstration dealing with the Efficient Use and Manipulation of the Microscope.—Dr. Marie C. Stopes: The Microscopy of Recent Coal Research.

THURSDAY, OCTOBER 25.

ROYAL SOCIETY OF MEDICINE, at 5.—Sir E. Sharpey Schafer: The Relations between Surgery and Physiology (Victor Horsley Memorial Lecture).

SOCIETY OF DYERS AND COLOURISTS (London Section) (at Dyers' Hall, Dowgate Hill), at 7.—I. E. Weber: Hydrogen Peroxide Bleaching.

FRIDAY, OCTOBER 26.

PHYSICAL SOCIETY OF LONDON (at Imperial College of Science and Technology), at 5.—S. H. Piper and E. N. Grindley: The Fine Structure of some Sodium Salts of the Fatty Acids in Soap Curds.—Dr. E. A. Owen and G. D. Preston: X-ray Analysis of Solid Solutions.—Dr. H. Chatley: Cohesion.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Sir Arthur Keith: The Distinction between Congenital and Acquired Forms of True Hernia.

NEWCOMEN SOCIETY (in Prince Henry's Room, 17 Fleet Street), at 5.30.—L. St. L. Pendred: The Value of the History of Technology (Presidential Address).

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—J. E. Saunders: Adventures with a Camera at the Zoo.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—A. V. Ballhatchet: Crystals for Wireless Reception.

PUBLIC LECTURES.

SATURDAY, OCTOBER 20.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Miss M. A. Murray: Tutankhamen and his Times.

MONDAY, OCTOBER 22.

UNIVERSITY COLLEGE, at 5.—Miss H. M. Holdsworth: The Problem of teaching Spoken English to Foreigners.

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, at 5.30.—H. G. Cannon: Some Biochemical Aspects of Animal Development. (Succeeding Lectures on October 29, November 5, 12, 19, 26, and December 3.)

TUESDAY, OCTOBER 23.

UNIVERSITY COLLEGE, at 5.30.—P. Fleming: The Care of School Children's Eyesight.

GRESHAM COLLEGE, BASINGHALL STREET, at 6.—W. H. Wagstaff: Geometry. (Succeeding Lectures on October 24, 25, and 26.)

WEDNESDAY, OCTOBER 24.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Prof. J. C. Drummond: Vitamins in relation to Public Health.

UNIVERSITY COLLEGE, at 5.30.—T. G. Hill: Illustration of Books.

THURSDAY, OCTOBER 25.

FINSBURY TECHNICAL COLLEGE (Leonard Street), at 4.—E. M. Hawkins: Analytical Chemistry (Streatfeild Memorial Lecture).

FRIDAY, OCTOBER 26.

UNIVERSITY COLLEGE, at 5.15.—B. Seebohm Rowntree: Factory Life as it is and as it might be.

SATURDAY, OCTOBER 27.

HORNIMAN MUSEUM (Forest Hill), at 3.30—E. Lovett: The Legendary Folklore of the Sea.

Science and the State.

AT the session of the Imperial Economic Conference on October 16, Lord Salisbury, Lord President of the Council, made a statement with regard to the Department of Scientific and Industrial Research. In the course of his remarks he said that it has become more and more accepted that the business of research is really an essential element in the industrial progress of the country. Notwithstanding that we all believe in private enterprise, a measure of Government intervention and research is requisite in this, as in many other things.

There are several phases of research which the Research Department has under its purview; for example, maintenance of industrial and commercial standards, work for Government services, and research for industrial purposes. As regards industrial research, while it is likely that the work of private enterprise will be more efficient than that of a Government department, on the other hand the Government possesses certain advantages. For example, the State can afford to finance researches which may prove to be so protracted as to be beyond the scope of private enterprise. Again, the Government has at its command an immense mass of accumulated knowledge. Thirdly, and this point of Lord Salisbury's is one which calls for comment, there is a large number of scientific men who are willing to work for the Government at far less than would be the remuneration of their great talents, and are willing through the Government to place their knowledge at the service of the community. If Lord Salisbury implies by this that the Government is willing and ready to trade upon the patriotism of a research worker, or upon his desire for the security of tenure which is so vital if he is to do good work, then it is truly a deplorable statement. Too often is it assumed that scientific men should be expected to work for the Government at less than would be the just remuneration of their services, though rarely are the mercenary advantages of the one-sided arrangement so baldly claimed by a responsible Minister.

Lord Salisbury went on to refer to the National Physical Laboratory as the outstanding illustration of the success of what in the long run is probably the biggest element of progress in industry, and that is research by the Government itself for industrial purposes. He stressed also as of Imperial importance the work of the Forest Products Board in connexion with timber, and of the Food Investigation Board on the transport of fruit overseas. Lord Salisbury concluded by paying a tribute to the business-like and economical administration of the Research Department.

Officialism in Education.[1]

The British Science Guild has issued a Memorandum on the subject of bureaucratic intervention in education, which, it states, has reached an acute stage and "has become detrimental to educational development and efficiency." The main charge made by the Guild is that official intervention in educational administration, as distinguished from efficient educational control, is now so excessive—both on the part of the Board of Education and Local Education Authorities—that governing bodies of Technical Institutions and Secondary Schools are becoming mere advisory bodies, without any freedom of action which would allow them to develop the individuality of their institution and take a lively and responsible interest in their progress. It is also pointed out that heads, appointed for their educational powers, are crippled by officialism, both as regards initiative and freedom to experiment on one hand, and on the other by the large demands for clerical work in the nature of "returns," which unduly curtails the time which they can devote to their proper work as educationists.

There have been similar protests from other sources. Local Education Authorities have themselves protested against the apparent endeavours of the Board of Education to assume greater control of matters which should be left to local discretion and to local knowledge. Here we find the British Science Guild accusing Local Education Authorities of acting similarly towards governing bodies of educational institutions. We have also heard of heads who have made similar protests against their governing bodies. We do not suggest that the protests are unwarranted. On the contrary, we think that there is much official intervention that is not only unnecessary and expensive, but is also detrimental to educational development.

We have an example in the working of the new scheme of national certificates in chemistry and in mechanical and electrical engineering, referred to in an article in Nature of July 14, p. 45. Apparently the scheme is designed to secure all the advantages of internal examinations and of reasonable freedom in the arrangement of the courses of work to meet local conditions and needs, coupled with just enough central control and assessment to secure the attainment of some uniform *standard* of work on which a national certificate can be issued, bearing the endorsement of the Board of Education and of the appropriate institution of chemists or engineers. The scheme is excellent, but we have reason to fear that before courses of study are recognised they are so modified—"mutilated" was one word which we heard—by the Board that they all bear a close resemblance to one another. If such be the fact, it is certainly an example of hampering local discretion and tending too much towards that machine-like uniformity beloved by bureaucrats, whose tendency is to worship at the shrine of organisation and to ignore the essential needs of educational progress.

We are not blind to the need of some measure of central control and to some sound and efficient organisation, but any attempt to standardise education, whether in school, technical institution, or university, is just as certain to put an end to progress as is the standardisation of any machine—like a motor-car, for example—bound to prevent any development or improvement in that particular machine. If the increased bureaucratic intervention which is complained of is tending to do this thing, then it must be resisted strenuously.

[1] Memorandum on the Increase of Bureaucratic Intervention in Education. (British Science Guild.)

The Lister Ward of Glasgow Royal Infirmary.

The managers of the Royal Infirmary, Glasgow, recently decided that, for various reasons, the celebrated Lister Ward of the Infirmary should be destroyed. It is not surprising to know that this decision has elicited many strong protests, and that an appeal has been made for the preservation of what is a unique relic in the history of medical science.

The ward in question was Ward 24 of the "New Surgical House," and was Lister's male ward from 1861 to 1869. It was the scene of his first attempts to apply the results of his studies on the healing of wounds to combating the septic disease which was rampant. By their success it became the birthplace of modern surgery. In 1912, when the reconstruction of the Royal Infirmary had advanced so far that the ward was no longer used, it was decided to pull down the block in which it is situated. Then a movement arose for its preservation as a memorial of Lister, and the managers of the Infirmary decided to keep it.

This decision the managers later rescinded, and the ward has really escaped destruction through force of circumstances. It was arranged as a museum, with relics and portraits of Lister and hospital furniture of the period, for the occasion of the visit of H.M. King George on July 7, 1914, and a few weeks later it was occupied by wounded soldiers from France. Now it is in use as cloak-room and reading-room for the women medical students. The relics, etc., are stored in the Pathological Institute, and it is hoped to use them in furnishing the ward, so as to illustrate some of the conditions under which Lister worked in it—a task of no great difficulty.

The sentimental value of the place is felt by those who teach in the Royal Infirmary and by their students and by visitors from abroad. No one questions the value of Burns's cottage at Ayr; yet apparently the

majority of the managers of the Royal Infirmary regard Lister's ward only as an obstruction.

Recently a pamphlet has been published by Mr. James A. Morris (Glasgow: MacLehose, Jackson and Co.), who, besides telling the story of the ward, shows that if the proposals of the Lister Memorial Committee were carried out, there would be practically no obstruction left. Actually, it is not the whole block which it is desired to preserve, but only the one ward itself, with three little rooms, which are an integral part of it and the basement below. Providentially, it would seem, this one of Lister's wards was on the ground floor. An appeal is being made to the managers of the Infirmary in the hope that a definite and strong expression, not only by members of the medical profession, but also by all those who cultivate science, as to the "historical and spiritual values of this famous landmark in the history of surgery," will convince them that the destruction of the ward would be regarded as a breach of trust, and its preservation as a simple act of respect for a memorial of achievements by which all civilised peoples have benefited.

The New Anthropology.

Tutankhamen and the Discovery of his Tomb by the late Earl of Carnarvon and Mr. Howard Carter. By Prof. G. Elliot Smith. Pp. 133. (London: G. Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., 1923.) 4*s.* 6*d.* net.

LAST year's discovery of a rich and varied collection of funerary equipment and other objects of Egyptian art of the time of Tutankhamen must inevitably reanimate the already vigorous discussion of cultural origins and the meaning of cultural symbols and uses. The prediction of the late Dr. W. H. R. Rivers in 1911 that the theories then advanced by Prof. Elliot Smith would be bitterly opposed by ethnologists of the older school has been abundantly fulfilled. Those theories attributed the creation of civilisation as we know it the world over to Egyptian initiative, and since their author has now himself entered upon the discussion of the recent discoveries in Egypt, the occasion is afforded for presenting a review of at least the chief lines of the argument developed with ever-increasing weight of detail during the past decade. For most of them reference need be made only to this admirable little volume written particularly to interpret the essential features in Egyptian custom and belief which found expression in Tutankhamen's time.

First, then, concerning Egyptian funerary ritual and its origins in the life of the early Egyptian community, the achievement of the new anthropology is twofold: with true imaginative power it has penetrated the veil of mystery and unintelligibility, which is the obscuring work of later ages, to the naïve realism of the early Egyptian mind, and, allowing the proved facts of early life in the Nile basin then to speak for themselves, it has provided us with a complete and consistent account of the rise and spread of our culture. Civilisation, for the new school, began when the early Egyptians invented the art of irrigation to extend artificially the area of cultivation of barley. The irrigation-engineer of early Egypt was the first man to organise the labour of his fellows. He conferred the benefits of security and prosperity upon the community and upon every individual member of it. He personified every subsequent idea of kingship. The life of the community flowed from him in a sense as real and actual as that in which the Nile was subject to his control. To identify him with these subtle forces was less an act of metaphysical ingenuity than one of unsophisticated realism. He became the incarnation of the life-giving powers which he bestowed upon his people. He became a god, assimilating to himself attributes of the shadowy Great Mother, and was apotheosised after death as Osiris. Eventually his powers were extended and transferred to his successor, Horus, himself credited with the immortalisation of the dead king. The whole of the elaborate equipment of Tutankhamen's tomb is inspired by this same motive: identification with Osiris and participation in his immortality and deification.

Funerary couches such as the three discovered last year, one representing a cow, the second a lion, and the third a hippopotamus, have been known previously from fragments and are among the most familiar objects represented in wall-paintings and upon papyri. In themselves they shed a flood of light upon the essential *naïveté* of the Egyptian mind at work upon the elaboration of our human beliefs; but also they focus attention upon an important chain of evidences concerning the migration of culture. The cow in Egyptian belief was not only the giver of milk, maintaining life in childhood and adult age, a foster-mother; she was also, even sixty centuries ago, the Divine Cow, identified with the actual mother of mankind, the Great Mother, Hathor, who was at one and the same time a cowrie, a grain of barley (both symbols of life-giving), a cow, and the moon. If the great giver of life and immortality were both a cow and the moon, she was then the appropriate vehicle to transport the earthly king heavenwards. The representation of this occurrence is a commonplace of Egyptian painting, and realism could scarcely be carried further than rhe representation in some cases of the very stars upon the belly of the animal. The lion-headed couch of the tomb is inspired by a like motive. The lion was Horus, the

son of Osiris, as well as the Divine Cow the function of which was to perform those ceremonies which would ensure the continued existence of the father. The hippopotamus, a symbol of the divine midwife, brought about the rebirth of the king whereby he became a god. Immortality was the sole distinctive possession of a god in early times.

The use of such vehicles for human transportation to the celestial regions is widespread and is everywhere determinative of deity. The whole conception is so peculiar and so much a part of a particular community experience that it is incredible that two peoples independently should have adopted its remarkable symbolism. Yet it is found to have spread throughout western Asia and the parts of Europe that came under the influence of Greek civilisation; India and eastern Asia; Indonesia and Central America. The general adoption of such a convention affords a striking illustration of the diffusion of culture, and since its origin in Egyptian beliefs is demonstrated, its presence in Syria and Mesopotamia, in Asia Minor and Syria and Greece, in India and eastern Asia, in Central America and Peru, is but a measure of the world's cultural debt to Egypt herself. In India the convention exercised an exceptional fascination over the minds of its ancient inhabitants, who, from about three or four centuries B.C. onwards, were accustomed to represent the vehicles of the gods in many different guises. Of these, one of the most interesting was the *makara*, the composite monster regarded as a crocodile but originally nothing more than the capricorn of the zodiac—the Babylonian combination of antelope and fish. In India, too, a great variety of the heads of other animals were substituted from time to time for the antelope's, notably the elephant's.[1] These evidences are but amplifications, on the cultural side, of the formidable array of facts, somatological and cultural, elicited earlier. Craniological evidence from Polynesia, the Malay Archipelago, the Asiatic littoral, and the Pacific coast of Central and South America accords perfectly with the facts concerning the geographical distribution of the practice and technique of mummification, of megalithic monuments, and of ancient mines. Mr. W. J. Perry[2] has not only related these two last-mentioned cultural records, but has also explained the motives which impelled small bands of civilised people to wander and to settle.

The statement has been made, and repeated as recently as the present year by prominent archæologists well acquainted with the facts, that the Egyptians were not a sea-going people; whereas we know from their literature that they did engage in maritime enterprise, and it is perfectly well established that they invented shipbuilding and were the builders of the first sea-going ships. It is equally definitely established that every other people in the history of the world who engaged in maritime traffic adopted the Egyptian conventions of both shipbuilding and seamanship. It is unreasonable to pretend that the transportation of the elements of early civilisation from Egypt to Syria and Crete and East Africa and Babylonia was not effected by the Egyptians themselves. In each of those places Egyptian colonists exploited natural products and planted the germs of Egyptian civilisation, which in the course of its development acquired certain local peculiarities. But from Crete and Syria and Babylonia secondary diffusions took place in most cases, no doubt without direct Egyptian participation. The recognition of cultural elements of Egyptian inspiration in India by no means involves the claim that either a single Egyptian or a single Egyptian word ever reached that country. The first is necessitated by the facts: the second is an unessential possibility. A Babylonian *element* colours the southern Indian culture; an Indian *element* that of Burma, Siam, and Cambodia. Behind all is the Egyptian origin and inspiration.

Most of the misunderstanding concerning the new theories has been due to a failure to understand the nature of such secondary diffusion. It cannot be made too clear that no claim has been advanced on behalf of direct transmission across great distances. The journeys may have been small, and few individuals may have achieved them, but the culture they bore with them was virile, and if degraded by change of hands, by time, and by racial and environmental as well as by merely geographical remoteness, it has not been degraded beyond recognition.

[1] Important evidence provided by the elephant-head in demonstrating the reality of the diffusion of culture so far as Scotland in the west and America in the east is set forth in correspondence in NATURE of Nov. 25, 1915, p. 340; Dec. 16, p. 425; Jan. 27, 1916, p. 592; Feb. 24, p. 703.

Glass-making in England.

Glass-making in England. By Harry J. Powell. Pp. x+183. (Cambridge: At the University Press, 1923.) 25*s*. net.

ANY one who takes the trouble to look through a catalogue of works in English dealing with the subject of glass will be struck with its poverty. For the most part, books on glass have been written by collectors and admirers of glass for other collectors and admirers, or by antiquarians and artists interested in stained glass. The number of books written by those intimately connected with the manufacture of glass, however, has been remarkably few. Since 1849, when Apsley Pellatt wrote his "Curiosities of Glass Making," giving an account of the processes of making all kinds

of glassware, the number of books of any note, written by persons having intimate acquaintance with the industry, can be counted on the fingers of one hand. Thus, W. Gillinder's unpretentious but, in its day, useful little book appeared in 1854; in 1883, H. J. Powell, to whom we owe the volume under review, was the chief author of a book on the "Principles of Glass-making"; while, since 1900, two other books have appeared giving some account of the manufacture of glass. It is doubtful if any other important industry has so poor a technical literature.

Now, for the first time, if we except A. Hartshorne's work on "Old English Glasses," published in 1897, we have a general history of glass-making in England, one, indeed, written by a manufacturer of specially rich experience and knowledge of the handicraft. It is a matter of great regret that he did not live to see the actual publication of the book.

The book gives, in the space of fifteen chapters, a general survey of glass-making in England. It carries us back to the Roman occupation, discusses such remains of this period as have been discovered, as also of the glasses of Anglo-Saxon date, but without arriving at any definite conclusion on the existence of a native industry before the thirteenth century.

It was in 1226 that we first meet with the definite and undeniable existence of the industry in Great Britain, at Chiddingfold in Surrey. The south-eastern counties of England, Surrey and Sussex in particular, appear to have been favourite spots for the native glass-makers during the thirteenth, fourteenth, fifteenth, and sixteenth centuries, largely on account of the presence of much beechwood, which was the favourite fuel of the glass-maker. The native productions during these centuries do not appear to have reached a very high level, and it needed the impetus of foreign workmen from the middle of the sixteenth century onwards to raise the art of glass-making in Great Britain, some of these workmen coming from Venice and others from Lorraine by way of the Low Countries. The moving spirits, however, who assisted most effectively in the English developments were most of them Englishmen, of whom Sir Robert Mansell in the first half of the seventeenth century was the most persistent of the pioneers in the industry, being responsible for the development of glass-making at Newcastle and mainly instrumental in introducing coal instead of wood as the fuel in glass furnaces.

One of the achievements of this period, namely, the first part of the seventeenth century, was the production of lead crystal glass, which constituted a contribution of fundamental importance to the industry and was destined, in virtue of its capacity to bear cutting and decorating, to supplant the famous Bohemian glass for ornamental purposes. By the middle of the eighteenth century the English crystal glass was already beating the Bohemian glass as that previously had beaten the Venetian.

Of considerable interest is chap. iv., on English drinking glasses, since it presents the view of a glass manufacturer and opposes various theories of glass collectors. Mr. Powell held the view, with which the reviewer heartily concurs, that connoisseurs have often attempted too much in endeavouring to assign dates and periods to articles of glassware on the basis of variety of form, of decoration, and of tint. Artistic development and skill varied so considerably from factory to factory that it was quite possible for different forms, both simple and highly developed, to be produced at contemporary factories; whilst it is a comparatively simple matter to reproduce tints in glass. Some factories, indeed, have made a study of the reproduction of antique glasses, and the author himself was responsible for some fine reproductions of Venetian glass.

Chap. xiv. is of special interest from the point of view of the scientific development of glass. It contains notes of the author's own experience as a glass manufacturer between the years 1875 and 1915, and the experiments recorded prove that there was at least one works in Great Britain which did not depend on rule-of-thumb methods. A study of the records of the provincial glass-houses (chap. vii.) shows that enterprise was by no means lacking, even during Government control (see chap. xii., the Excise Period), when it was a matter of surprise that men could still be found to carry on glass manufacture under the conditions prescribed by law, which insisted that notice in writing must be sent to the Excise Officer before any of the important operations of glass-making could be carried out.

Not unnaturally, the main portion of the book is concerned with glass-making as an art. As a handicraft the author's view was that glass-making was doomed. He states so quite definitely in the preface; and, whether his view be correct or not, it was the chief factor at any rate which induced him to write this account. The disappearance of glass-making as a handicraft and the introduction of the machine, however, did not necessarily mean to him the final loss of the artistic in glass. He says: "If mechanically produced tableware is inartistic and ugly the fault lies with the designer. . . . Designs, whether for hand-made or mechanically produced tableware must be evolved from an intimate acquaintance with the nature of molten glass and the technique of manufacture rather than from the superior inner consciousness of the art school."

Several of the chapters of the book were written as lectures or as journal articles, and in some ways the book is therefore disjointed, whilst some of the chapter

headings do not convey the correct idea of the contents. Thus, one chapter (chap. x.) is devoted to the records of the famous Whitefriars factory, but its chief title is "Flint Glass." The chapter on "Old London Glass-houses" (chap. vi.) and that on "Provincial Glass-houses" (chap. vii.) both contain much detailed information, including such references as occur to the investigations of Faraday, Harcourt, and of Stokes on optical glass, and, indeed, to the whole subject of optical glass—except the brief reference later on to War developments.

One would like to have seen included some account of trade union influence in the nineteenth century, and something more about the condition of the industry in the last fifty years than the statement that it was in "a parlous state," while the concluding chapter (chap. xv.) on "Glass-making during the War" is somewhat sketchy. It may be admitted that the War developments gave a suggestion of what the future might be, and perhaps it was best that the detail should be left for the younger generation of men to fill in.

There is no existing book to which the one under review can be rightly compared. It stands as a definite and valuable contribution to our knowledge of the history of glass-making in Great Britain. The book is well got up and illustrated, containing one hundred and six illustrations, mostly photographic reproductions. W. E. S. TURNER.

Fungi and their Spores.

Researches on Fungi. By Prof. A. H. Reginald Buller. Vol. 2: Further Investigations upon the Production and Liberation of Spores in Hymenomycetes. Pp. xii+492. (London: Longmans, Green and Co., 1922.) 25*s*. net.

PROF. BULLER'S original volume, entitled "Researches on Fungi," was published in 1909, and with its distinctive point of view and original observations attracted considerable attention among botanists. The author, in the preface to the present volume, states that it is to be considered as volume 2 of the original work, and that volumes 3 and 4 are in an active state of preparation. Such industry is itself remarkable, but such productivity in book publication is even more so at the present time, and is explained by the generous help towards publication provided by the Canadian National Council for Scientific and Industrial Research. The Birmingham Natural History and Philosophical Society has made a grant towards the cost of reproduction of the illustrations in the present volume, which include many beautiful photographs as well as a number of the author's original and extremely helpful diagrams.

The volume divides sharply into two sections. The first eight chapters are very diverse in character. They exhibit the author again as a born naturalist, making full use of the resources of a modern laboratory to extend the range of his interesting field observations. But it must be confessed that a certain diffuseness and prolixity make these early chapters difficult reading. Some of the material has been published before in the Transactions of the British Mycological Society, notably the chapters on slugs and squirrels as mycophagists, and all this early section might gain by condensation.

Chapters ix-xiii are very different in character. They include a most interesting attempt to interpret the organisation and development of the hymenium of the Agaricineae. In 1911 the author commenced this investigation upon the common mushroom, *Psalliota campestris*. Experience proved this plant an unsuitable starting-point, but realising the significance of the mottled appearance of the gills of Panaeolus, Prof. Buller worked out the progressive development of successive series of basidia and spores, in different phases in contiguous irregular areas on the mottled gill, and thus was successful in presenting a most complete analysis of the hymenial organisation. *Stropharia semi-globata* was similarly and most completely worked out, and incidentally might prove a better class object for the elementary student than the common mushroom, which only yielded up the secrets of its organisation when Prof. Buller returned to the attack armed with experience gained upon these other types. In this and the succeeding volumes the author promises an analysis of the two main types of hymenial organisation, that of Panaeolus and of Coprinus, and of the various sub-types he has distinguished.

This work must form the basis of laboratory study and teaching on the Agaric hymenium for many years to come. Interpretation throughout the work is entirely teleological, and while this permits a biological significance to be attached to many of the facts presented in so interesting a fashion with almost suspicious facility, it leaves the way open for a later reinterpretation of fungus organisation based upon a fuller knowledge of the complex machinery of heredity and growth and its relation to environment.

Geodesy and Geodynamics.

Naturwissenschaftliche Monographien und Lehrbücher. Vierter Band: *Einführung in die Geophysik*. Von Prof. Dr. A. Prey, Prof. Dr. C. Mainka, und Prof. Dr. E. Tams. Pp. viii+340. (Berlin: Julius Springer, 1922.) 12*s*. 6*d*.

THE title of the work under notice is a little misleading, and might better have been "An Introduction to Geodesy and Geodynamics," considering

that it contains no reference to such important branches of geophysics as terrestrial magnetism, earth currents, auroræ, and atmospheric electricity, not to say meteorology. Within its chosen limits, however, it affords a welcome summary of a considerable body of knowledge concerning the earth, which has not hitherto been accessible in anything like so concise and handy a form.

The work is divided into three parts, by different authors, but is as unitary a treatise as can be expected in the case of a wide field of rather loosely-connected studies such as geophysics. The first part occupies more than half the volume, and is distinguished from the two later parts by its largely mathematical character; it deals with the figure of the earth, the theory of tides and seiches, and the density and rigidity of the earth. The determination of the geoid by triangulation is first briefly explained, including an account of the essential features of the instruments used and the methods of reduction. The application of gravity measurements to the same problem is then dealt with; a short summary of potential-theory is followed by a description of the instruments and methods used in gravity-determinations, both absolute and relative; Clairaut's theorem connecting the ellipticity of the earth with the ratio of gravity at pole and equator and of gravity with centrifugal force at the equator is proved and discussed in connexion with observations for the north and south hemispheres separately. There is a brief chapter on measurement of heights above sea-level, by levelling, trigonometrical surveying, and barometric observations, followed by a longer but condensed summary of the changes of level of the sea itself; the tide-producing potential of the moon is developed, following Darwin in the main (not even a bare reference is made to the important work by Proudman and Doodson in this field), and the equilibrium theory, Laplace's dynamical theory, and Airy's canal theory of tides are summarised. Tidal currents and seiches are also touched on: the important influence of barometric pressure scarcely receives sufficient mention. The first part of the book ends with a long and interesting section on the constitution, mean density, and internal pressure of the earth; the basis and conclusions of the theory of isostasy are explained, and the various lines of evidence bearing on the rigidity of the earth are well summarised.

The second part of the book relates to seismology, and rapidly reviews the instruments used, the records obtained, and the conclusions thence derived as to the path and speed of the longitudinal and transverse waves, and the bearing of this evidence on the theory of the constitution of the earth.

The third section will probably be the most interesting to the majority of readers of the book, because it deals in a non-mathematical, discursive way with the borderland region between geodesy and geophysics. There the causes which have led to the present surface features of the earth are discussed. Without accepting Wegener's theory of continental displacements, the author adopts the broad principle that large lateral displacements of continental blocks must be taken into account in geology, though discounting the very uncertain astronomical evidence thus far adduced in favour of measurable rates of variation of relative longitude. Considerable space is also devoted to the causes of vulcanism and of earthquakes.

Our Bookshelf.

Civil Engineering Geology. By Cyril S. Fox. Pp. xvi + 144. (London: Crosby Lockwood and Son, 1923.) 18*s.* net.

A civil engineer laid the foundations of modern geology; it is therefore singularly inappropriate that civil engineers should be somewhat dependent upon the geologist for decisive opinions on the geological aspects of engineering schemes. The author would attribute the engineer's diffidence in the matter of geology to the air of specialisation with which an awesome nomenclature has invested the subject. Engineers are themselves rather at fault in having allowed the cloak of William Smith to descend on others' shoulders. The geology of field operations involves little more than a common-sense application of first principles to special types of observations made on the engineer's own ground.

Geology is now, however, a subject studied by most engineering students, who are well equipped for the study. The author's purpose is to induct civil engineers to a territory which they might have shared equally with geologists from the first, and this purpose is achieved in an inspiring book; it deals in a thoroughly practical way with geology from the engineer's point of view, and is in no sense a slender original design erected on a trimmed mass of material quarried from other works—the author's published work excepted. A brief introduction leads directly to the problems of water supply (Pt. I.); Pt. II. deals with field operations, Pt. III. with building materials. From first page to last the book bears the stamp of experience and practical acquaintance with engineers' problems. Illustrations include sketches taken from the author's field notebook; that a few of these are truly "sketchy" is less a defect than a positive merit, which the engineer will promptly recognise. Criticism can be directed only against their scale. These sketches are supplemented by numerous structural sections and photographs.

Assuming the reader is not familiar with geology, the conventional methods of representing the commoner rock types should receive early mention; the need for the "key" is urgent in Figs. 13-18; it is first given in Fig. 24. Similarly the terms strike, anticline, etc. which are freely used in Pts. I. and II. are defined in Pt. III., and rock classification is attacked before rock-forming minerals have been described. The author outlines a new scheme of rock classification which will

appeal to petrologists no less than to engineers. The inclusion of nephelinite under syenites is a slip which, with a few others, will doubtless be corrected later.

A. B.

An Advanced Course of Instruction in Chemical Principles. By Arthur A. Noyes and Prof. Miles S. Sherrill. Pp. xviii+310. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1922.) 18*s.* net.

PROFS. NOYES and SHERRILL have produced a work which might be mistaken at first sight for yet another text-book of physical chemistry, since it deals with such subjects as vapour-pressures, osmotic pressures, electrolysis, chemical equilibrium, chemical change, and the phase rule. A closer study of the book reveals the fact that it is quite distinct, both in its purpose and in its method, from the ordinary text-books of descriptive physical chemistry. This contrast is shown not only by what the book contains but also by what it omits. Thus, the newer theories of the structure of atoms, molecules, and crystals have been reluctantly omitted, in spite of their interest and importance, since on the chemical side they are mainly empirical, the general principles (if any) on which they are based being mathematical and physical rather than chemical.

A clear view of the purpose of the book is obtained by studying the series of problems which it contains. These are not merely supplementary to the course of instruction but are its most important feature. The total number of these problems is nearly 500; but suggestions are given for a shorter course when the time available is too short to cover the whole of the syllabus. In some respects the book recalls Nernst's "Theoretical Chemistry," although it is in some ways a more attractive book for the student. Thus the whole of the text is contained in less than 300 pages; and the English student has the advantage of reading it in the original language instead of in a translation. From the point of view of the teacher of chemistry, the problems on which the book is based are of importance as ensuring that the student really understands what he is being taught, and is able to apply it in a direct way to chemical problems. It is indeed difficult to imagine any course that would be of more value to the student of physical chemistry in enabling him to secure a real mastery of his subject; and this fact more than compensates for the absence of the more popular features which can be used to add to the attractiveness of a descriptive text-book.

Studies in Religion, Folk-lore, and Custom in British North Borneo and the Malay Peninsula. By I. H. N. Evans. Pp. viii+299. (Cambridge: At the University Press, 1923.) 20*s.* net.

MR. EVANS, now curator of the Taiping Museum, includes in this book notes collected during two series of explorations. The first part describes his investigations in the Tuaran and Tempassuk districts of North Borneo; the second deals with the customs and beliefs of the woolly-haired Negritos, the wavy-haired Sakai, and the Jakun pagans of the Malay Peninsula. This latter may be regarded as a supplement to Messrs. Skeat and Blagden's "Pagan Races," and Mr. Skeat's "Malay Magic." In North Borneo the coast districts are occupied by the Bajaus and Illanuns, proto-Malayans, but the Dusan pagans of the interior naturally attracted Mr. Evans's special attention. He gives an excellent description of the beliefs and customs of this interesting race. Much of his account of their religion, folklore and customs, and of head-hunting, now happily obsolete, may be compared with the records of other explorers in these regions.

The method of Mr. Evans wins our confidence. He gives the actual notes of his work and the sources of his information, without any attempt at generalisation, which is particularly dangerous when dealing with isolated communities where the culture varies from one valley or jungle to another. Even in the Malay Peninsula he has been able to add something to the harvest already garnered by Messrs. Skeat and Blagden. The folk-tales are mostly concerned with animals and their ways, and supply interesting parallels to those current in adjoining regions.

The Elasmobranch Fishes. By Prof. J. F. Daniel. Pp. xi+334. (Berkeley: University of California Press. 1922.) 4.50 dollars.

As the author reminds us in his preface, of all living fishes the Elasmobranchs are by far the most interesting and important for the understanding of the Vertebrata. In this handsome and beautifully illustrated volume Prof. Daniel gives a general account of the sharks and rays chiefly from a morphological point of view, though not neglecting the relation of structure to habits and food. Each of the eleven chapters dealing with the external form and the anatomy of the various systems of organs begins with a very clear description of *Heptanchus maculatus*, followed by a comparison with other more specialised forms, and concludes with an adequate bibliography. Thus the reader is presented with an excellent survey of the range of structure presented by the whole group. Matters of fact are very accurately stated, but in dealing with theoretical deductions of a more general nature, the author seems to be on less certain ground. One serious blunder only have we met, on p. 309, where the kidney tubules are called "nephridia." Surely it is now recognised that these tubules, derived from the cœlomic wall, have nothing to do with the true nephridia of Amphioxus and the cœlomate Invertebrates, but are rather to be compared to the cœlomoducts so constantly found in the latter? Prof. Daniel is to be congratulated on having produced a most instructive and attractive book which should prove useful both to students and to teachers of zoology.

The Story of the Maize Plant. By Prof. P. Weatherwax. (University of Chicago Science Series.) Pp. xv+247. (Chicago: University of Chicago Press; London: Cambridge University Press, 1923.) 1.75 dollars.

THIS volume serves to gather together in a convenient form much of our scattered knowledge of the maize plant, and provides a concise summary of the general history of this important food and forage crop. The accounts of the morphology, anatomy, and ecological relations of maize lead up to an exposition of methods of cultivation and harvesting, followed by a detailed description of the flowering organs and the development of the grain or seed. The author indicates the

great possibilities of improvement in quality of seed that might be brought about by a judicious application of the principles of plant breeding.

Maize would appear to have been much valued in aboriginal America, but with the great increase in colonisation which followed the voyage of the *Mayflower* it has steadily increased in importance until now the United States produce three-quarters of the total world-crop.

A special feature of the book is the excellence of some of the original text figures, which are both clearly drawn and well reproduced, being among the best hitherto published for this plant. The aim of the book, with others in the same series, is to reach the educated layman as well as the specialist, and the volume offers a useful and interesting résumé of the subject dealt with.

Supplying Britain's Meat. By G. E. Putnam. Pp. 169+16 plates. (London, Calcutta and Sydney: G. G. Harrap and Co., Ltd., 1923.) 5*s.* net.

Mr. G. E. Putnam is the consulting economist to Swift and Company, Chicago. Of the seven chapters of his book, the first three, and possibly the sixth, deal with the subject selected for the title of the book. The remainder are devoted to an economic justification of the big-scale United States businesses dealing with the distribution of meat and meat products, and to a defence of their conduct as stated in the official reports of American commissions, and the large volume of unofficial criticism from the American public.

From the British point of view, the most significant fact is that only 60 per cent. of the beef, and 50 per cent. of the mutton consumed in Great Britain is home-grown, and there seems little possibility of the home supplies even maintaining this proportion in the future. The manner in which this deficiency in home supply has been met by Imperial and foreign shipments is very well traced out. The sections dealing with the distribution of imported meat contain a detailed defence of the middlemen. The author believes that they perform indispensable economic functions, and further, their work cannot be done efficiently unless they are units in an organisation in the closest touch with the firms of meat exporters.

Letters of a Radio-Engineer to his Son. By John Mills. Pp. vi+265+12 plates. (London: G. Routledge and Sons, Ltd., 1922.) 10*s.* 6*d.* net.

At the present time practically every student at a technical college, and most school-boys, are intensely interested in radio communication. The author takes advantage of this and writes a book in familiar language as an introduction to understanding the latest developments of the art. He expends no time in describing fluid theories or pith balls. He plunges at once into describing protons and electrons and, provided his reader consents to follow him, shows what an essential part they play in radio apparatus. How to measure an "electron-stream" and "electron-moving-forces" are simply described. Inductance and capacity, tuning and resonance and the harmonics in the human voice are explained. Broadcasting stations, trans-Atlantic telephony and the telephone circuit with its amplifying stations connecting New York and San Francisco are also described. The author, who is a well-known expert of the Western Electric Co., concludes by pointing out how excellently ordinary telephony and radio telephony can be united so that the voice vibrations can be carried over wires and across wide spaces before they come to the receiver. The two methods use the same general principles and much of the apparatus used is common to both.

Epping Forest. By E. N. Buxton. Ninth edition revised. Pp. xiv+182+6 maps. (London: Edward Stanford, 1923.) 2*s.* 6*d.*

The ninth edition of this little book, which has been out of print since 1915, is very welcome. It contains a history of Epping Forest, with an account of the topography, accompanied by several coloured maps. Other chapters follow on the animals, birds, insects and pond life of the forest area, as well as the trees, flowering plants, mosses and fungi. A short chapter gives an account of prehistoric man and the animals he hunted. Another is devoted to the geology of the district. A final chapter has been added on the management of such a forest. It will no doubt be found useful by students, naturalists and others who visit Epping Forest and wish to know more of its natural history.

The Chemistry of the Inorganic Complex Compounds: an Introduction to Werner's Co-ordination Theory. By Prof. R. Schwarz. Authorised translation by Dr. L. W. Bass. Pp. x+82. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1923.) 8*s.* 6*d.* net.

This book is a translation from the German of an introduction to the study of co-ordination compounds. It is an excellent little book for the purpose, and even advanced workers in this branch of chemistry will find it of value on account of the fact that a reference to the original literature is given in the case of all the compounds that are referred to throughout the book. The form in which the book is issued is very attractive, and it should have a large circulation among English readers.

Handbook of Steel Erection. By M. C. Bland. Pp. ix+241. (London: McGraw-Hill Publishing Co., Ltd., 1923.) 12*s.* 6*d.*

There are but few books dealing with this subject, and for the most part treatises on structures do not give adequate treatment to the methods of erection. The volume before us gives both descriptions of these methods and also the calculations involved in determining the strengths of the appliances used. Civil engineering students will find the book a useful supplement to their text-books on structures.

The Unconscious: an Introduction to Freudian Psychology. By Israel Levine. Pp. 215. (London: Leonard Parsons, Ltd., 1923.) 7*s.* 6*d.* net.

An excellent short account of the Freudian theory in its general philosophical aspect. The author finds no need to force on the reader unpleasant descriptions of particular neuroses, and he treats the whole concept of the unconscious as a metapsychology. Its relation to older classical conceptions and to modern rival theories is briefly but quite clearly indicated.

Letters to the Editor.

X-rays and Crystal Symmetry.

MR. T. V. BARKER directs attention (NATURE, October 6, p. 502) to the difficulties that may arise in the classification of crystals in consequence of the use of the X-ray methods of analysis, since the latter take note of features in crystal structure which are not always the same as those from which the older methods draw their deductions. From the same point of view he discusses also the existence of the molecule in the crystal.

It is to be remembered that all inquiry must be directed to the determination of the relative positions of the atoms and the molecules within the unit of pattern, and of the forces which they exert on one another. The nature of the symmetry of the crystal and the possible existence of the molecule are questions of academic interest only, except in so far as they contribute to this end. From this point of view the difficulties described by Mr. Barker seem to lose much of their importance.

The symmetry determinations of the older and well-known methods are complete when the crystal has been assigned to one or other of the thirty-two classes: and this can generally be done, though there often remains some uncertainty. On the other hand, the X-ray methods determine the form and size of the unit of pattern and the number of molecules which go to the making of it. It is an open question which only experience can answer, whether the X-rays give absolutely correct evidence on this point: whether, for example, they might overlook some difference which, repeated at some multiple of the spacing determined by the rays, implied a larger unit of pattern. The difference might be of such a kind as to be incapable of detection however great it might be, or it might be missed merely on account of insufficient magnitude. So far, the evidence points to the possession by the X-rays of the power to detect any material difference: they can, for example, make apparent the difference between two neighbouring atoms of carbon in the diamond which are due only to differences in the orientation of their attachments to their neighbours. Moreover, the X-rays give such information as to the relative positions of the atom-groups into which the crystal unit may be divided that the crystal can not only be assigned to its proper class, but also to its proper type among the two hundred and thirty possible types of structure, as defined either by the space group of symmetry movements which the crystal possesses or by the arrangement which the X-rays have found. There is only one exception of importance. The X-rays cannot in general determine whether a crystal has or has not a centre of symmetry: and this sometimes leaves the alternative as to whether a crystal belongs to a certain type of symmetry in a lower class or to another type in a higher class obtained from the lower by adding the centre of symmetry. If it is known from observation of form or otherwise whether there is or is not a centre of symmetry the ambiguity disappears.

The general arrangement of the molecules having been found, any further observations of the form or other physical properties of the crystal have a value not because they may put the crystal up or down by a whole class, but because they help in the interpretation of the structure as it has so far been discovered.

So far as present experience shows, the atom group referred to above has the same composition as the chemical molecule: though it is not to be expected that it should have exactly the same form. In rock salt it is possible to associate with the sodium atom any one of the six chlorine atoms that surround it and to say that here is the molecule: or it may be said, if preferred, that the molecule has disappeared. In an organic crystal, naphthalene for example, there is one atom group which may with some justice be described as the molecule. Even here, however, many of the carbon atoms have two hydrogen neighbours, one of them belonging to the molecule to which the carbon atom belongs, and one to a neighbouring molecule. Is there any difference in the nature of the attachment of the carbon to the two hydrogens? If there is, then there is definitely something which may be looked on as the molecule since there is a group which has the same composition as the free naphthalene molecule and would actually form such a molecule on the dissolution of the crystal, though the shape might be slightly changed. If not, then it might be said, as of the diamond, though to a lesser degree in this case, that the whole crystal was one molecule. The position of the hydrogen would be an example of "co-ordination." The nature of the hydrogen attachments is obviously of the highest importance; and we may hope to learn more about it by further experiment. Only in that light, however, is there any interest in discussing the question of the existence of the molecule in the naphthalene crystal.

W. H. BRAGG.

The Optical Spectrum of Hafnium.

IN our letter to NATURE of March 10, 1923, we gave a preliminary list of the most prominent lines between 2500 and 3500 Å. U. in the arc spectrum of the new element hafnium, discovered by Coster and Hevesy (see NATURE, January 20, February 24, April 7, 1923). In this list we included only lines of intensity of 2½ and more, using a scale of intensity from ½ to 6. Prof. Hevesy has now been able to supply us with a pure hafnium preparation containing according to X-ray analysis not more than about 1 per cent. zirconium, and in addition small traces of titanium, manganese, and niobium. With this preparation we have photographed both the arc and the spark spectrum of hafnium. As to the arc spectrum, we have controlled all our older measurements of the published lines, and also of the weaker unpublished lines, and have added to these a considerable number of still weaker lines.

The spark spectrum does not seem hitherto to have been examined. On the other hand, Bardet (*Comptes rendus*, t. 176, p. 1711, 1923) a short time ago published a list of lines belonging to the arc spectrum of hafnium in the region between 2300 and 3500 Å. U. As it is not stated and cannot be inferred whether his lines are given in the international or in the Rowland scale, it is sometimes difficult to decide whether a line in his table coincides with one of our lines or not. As all his lines with the exception of 6 are stated as "moyenne," "faible," "extrêmement faible," "à peine visible," we think that his preparation was not very concentrated. As a whole, the two spectra are not very different; yet Bardet does not find all the stronger lines given in our first table, which (with one exception) are now all confirmed, and the relative intensity of his lines are rather different from ours. This seems to indicate that the hafnium spectrum can

differ much according to the conditions of excitation. This also, as is well known, is the case with the zirconium spectrum.

The spectra were photographed with the same instrument as before, and the arc spectra were produced in the way previously described; the spark spectra were obtained with a large induction coil between carbon electrodes saturated with the hafnium salt solution. In the table above we give the hafnium lines in international Å. U. in air measured against iron normals, and an estimation of their relative intensity I, both in the arc and in the spark spectrum (scale ½ to 6, lines weaker than 1 omitted; 6 denotes very strong, 5 strong, 4 rather strong, 3 not strong, 2 faint, 1 weak, ½ extremely weak, *d* diffuse). The wave-lengths are given to 0·05 Å. U., the accuracy which is generally reached; at the longer wave-lengths an error of about 0·1 Å. U. may be possible. Where (Ti), (Mn), (Nb), or (Zr) is added it means that the line in question is nearly coincident with a line belonging to the spectrum of one of these elements, traces of which we have mentioned were present, but that the line is so much stronger relative to the other lines of that element present in the spectrum that it is almost certain that the line really belongs to the hafnium spectrum.

* In our former letter erroneously given as 3097·75.

A similar examination of the hafnium lines in the remaining part of the spectrum which is obtainable photographically, will appear shortly. We publish this table first, because it comprises the region in which high accuracy is easily reached by smaller spectrographs, and will therefore mainly be used for identification, as the hafnium spectrum shows few characteristic lines in the visible part of the spectrum.

The Isotopes of Lead.

IT was suggested by the writer in 1912 that the end-products of the uranium and thorium disintegration series should differ in atomic weight from that of common lead, which chemically they closely resemble. As the atomic weights of these products, determined experimentally later by Richards and others as approximately 206 and 208 respectively, "bracketed" the atomic weight of common lead, it was not unreasonable to suppose that common lead is a mixture of isotopes of which the mass-numbers 206 and 208 are chief. This, although probable, is still unproved. The further deduction that conceivably lead in Nature has been mainly produced by the disintegration of uranium and thorium has received some, but not a great measure of support. If it could be shown experimentally that common lead has some isotopes which are not likely to be produced by disintegration, this hypothesis would be more difficult to maintain; if the difference were complete the hypothesis would be disproved.

My analysis of the complexity of elements, of which some account was given in NATURE of October 20, leads logically to the conclusion that common lead consists principally of mass-numbers 204, 205, 206, 207, 208, and 210, of which probably 206 and 208 are chief. This is surprising since the mass-numbers of isotopes do not differ generally by more than 8 units, and radium B weighs 214. Most of these numbers may also be derived from Aston's published results for the isotopes of elements 18, 34 and 50, the atomic numbers of which, like lead, are of the form $16n+2$. In addition, the mass-numbers 205 and 207 are deducible from this consideration: an element of even atomic number z may have an isotope of odd mass-number a apparently only when the difference $a-2z$ is unique. The differences 3, 5, and 7 do not appear to belong to any element,

but 9, 11, 13, 15, 17, 19, 21, 23, 25, 27, 29, 31, 33, 35, 37, and 39 may be most probably assigned to elements 34, 36, 44, 48, 50, 50, 54, 54, 60, 64, 66, 66, 70, 70, 76, and 80 respectively. (The results for elements 34, 36, 50, 54, and 80 are Aston's.) If this be accepted, it follows that the differences 41 and 43 belong to element 82, because (*a*) the mass-number 201 appears to be unstable (being the head of a series of unstable mass-numbers 201, 157, 113, 73, and 33), and therefore 41 cannot be assigned to element 80; and (*b*) because it is to be expected that element 82, like 66 and 50, has two odd isotopes. These are in consequence 205 and 207.

Of the six isotopes mentioned above, 206, 208, and 210 are end-products of radioactive series; possibly 207 is also; so that this analysis, if confirmed experimentally, cannot by itself claim to dispose of the view that common lead may be of radioactive origin. But neither does it necessarily support it; the matter is still left open.

It is not unlikely that the odd mass-number 205 is an isobare, because thallium ($z=81$) is likely to consist of mass-numbers 203 and 205, not only because its atomic weight lies between these numbers but also from the analysis in my last letter. Aston, by showing that mercury has probably an isotope of 197, first established the possibility of the existence of odd isobares in the inactive elements, since it is very probable that gold's principal isotope is 197 also. But, in general, odd isobares are likely to be rare among inactive elements, but not impossible, as I said.

Neodymium, dysprosium, and ytterbium were not mentioned in my last letter. The chief isotopes of the first of these appear to be 142, 144, 145, and 146, possibly 148 and 150 also; of the second, 160, 161, 162, 163, 164, and possibly 166; and of the third 172, 173, 174, 175, 176, and possibly 178. I should like also to make a few minor alterations to previous statements. Lanthanum is apparently not simple but includes (possibly very little of) 137; gold is not likely to have 199; holmium is mainly 165. Tellurium should contain 122. But as I have now been able to calculate simply both unstable mass-numbers and even isobares, details are not of first importance.

It is not asked that any of the mass-numbers of this or of the previous letter should be accepted before being disproved or confirmed by experiment. But they are of interest as being the most probable numbers obtained by a simple and straightforward consideration of the facts of radioactivity on the reasonable assumptions stated.

A. S. Russell.

Dr. Lee's Laboratory, Christ Church, Oxford, October 13.

Problems of Hydrone and Water: the Origin of Electricity in Thunderstorms.

Prof. Armstrong's friendly criticism (Nature, October 13, p. 537) of my theory of the origin of electricity in thunderstorms seems to neglect the fact that my explanation of thunderstorms is based entirely upon experimental and observational evidence. If experiments can be said to prove anything, then my work and the work of others has shown conclusively that: (*a*) if there are ascending currents exceeding 8 metres per second in the atmosphere, there must be a great deal of breaking of rain drops; (*b*) every time a water drop breaks there is a separation of electricity; (*c*) the broken water drops retain a positive charge; (*d*) the air attains a negative charge. On the other hand, observations have shown that there is a considerable excess of positive electricity brought down by rain. These are all tangible facts which any one can test by making the suitable experiments, and I have done nothing more than arrange them into such a form that a reasonable account of the phenomena of thunderstorms results.

Surely Prof. Armstrong does not wish to suggest that all this work is wrong because it does not fit in with his theory of hydrones. He cannot expect us to neglect the evidence that electricity is produced when drops break, because, according to his theory, it appears more likely that electricity would be produced when drops combine.

What alternative has he to offer to a theory which has met with very wide acceptance? He says: "Assuming that my interpretation be correct, may not the great rise in potential required to produce lightning have its origin in the coalescence or cooperation of minute drops charged by an external source?" This is very depressing, for it throws us back to where we were twenty years ago, with an unknown "external source" of electricity and erroneous ideas of the increase in the potential of a cloud due to the coalescence of the drops.

G. C. Simpson.

Meteorological Office, London.

The Occurrence of Urease.

Letters on the occurrence of urease are printed in Nature of August 11 and September 22. In the former, Prof. Werner reports that he has found urease in all the leguminous nodular growths he has tested; in the latter, Prof. Beijerinck describes how he has detected the enzyme in *B. radicicola*. Prof. Werner writes: "So far as we have been able to ascertain, the peculiar root nodules of leguminous plants have not hitherto been tested for urease." I reproduce, therefore, the following passage from an article on "The Function of Hormones in regulating Metabolism," by my son and myself, published in the *Annals of Botany*, vol. xxv., No. xcviii., April 1911.

"Lastly, we may refer to the nodular growths on the roots of leguminous plants; these are known to be most essential to the proper growth of the plant but their function is by no means clear; it is well known that they are the seat of bacteroids and it may be that these function as assimilators of atmospheric nitrogen gas and convert it into ammonia; or it may be that they exercise digestive functions and serve to 'deamidate' amino-compounds. At all events, they are distinctly alkaline, whereas the root sap is acid. Moreover, it has been shown by Hutchinson and Miller, that, when distilled with magnesia under reduced pressure, the nodules furnish more ammonia than do the roots (0·043 per cent. against 0·016 per cent.). We suggest that some part at least of the influence exercised by the nodules may be due to their aminogenetic power. We propose to make this assumption the basis of experimental inquiry."

Then, I would direct attention to the British Association Report, Australia, 1914, where, at p. 109, the following passages are to be found, at the end of the Report of the Committee for the Study of Plant Enzymes.

"In view of the presence of ammonia in the nodular growths appearing on the roots of Leguminosæ, it appeared probable that the enzyme Urease would be found in these. It has been detected in the nodules from Lupins and a number of other Leguminosæ. Attempts to detect the enzyme in organisms cultivated from the nodules have thus far been attended with negative results.

"Mr. Benjamin, working at Hawkesbury Agricultural College, near Sydney, Australia, has detected urease in nodules from several Australian plants, including wattles; also on tubercles derived from the

Cycad, *Macrozamia spiralis*. He has found urease also in the seeds of *Abrus precatorius*."

The earlier experiments referred to were my own. Mr. Benjamin had assisted Mr. Horton and me in our work on urease, published early in 1913. He was a young Australian and he undertook the observations, on his return, at my request. When in Java, in September 1914, I had the opportunity, at the Buitenzorg gardens, of testing fresh Abrus seeds and of confirming Benjamin's result. I may say, the amount present is small, in no way comparable with that in Soja beans.

To me the presence of urease in the nodules is little short of a matter of course—in view of their "ammonicity." The interest of the observation lies in the possible application thereof.

Urea is foreshadowed as the nitrogenous fertiliser of the future but apparently it has its limitations. All soils, all plants, do not respond to it equally. I was told years ago, that it is particularly good for Pease. Why, Mr. Peasecod? Probably it is not operative as such but merely as a source of ammonia and must be hydrolysed to make it available. Only soils which contain urease would respond. A clover-sick soil may well be wanting in the organisms which give rise to the nodular growths.

To be practical—it would seem to be desirable to test the comparative effect of urea on the growth of non-leguminous plants when grown with and without a leguminous plant, such as clover.

Henry E. Armstrong.

Colour Vision and Colour Vision Theories.

In the first of my two recent letters on this subject I selected five of the cases in which Dr. Edridge-Green asserts that the trichromatic theory cannot explain certain phenomena of colour vision; and I indicated, in each case, the source of his error. In more than one case I gave the full proof. In his reply he took no notice of these proofs except in so far as he seemed to admit their accuracy. But he brought forward three other cases, asserting incompetence of the trichromatic theory in connexion with them. In my second letter (Nature, September 8) I similarly indicated the oversight involved in each of these three additional assertions.

I must confess, therefore, to some degree of surprise that Dr. Edridge-Green, in his letter appearing in Nature of September 29, should say that he will deal with my explanations regarding the competence of the trichromatic theory when I give them. They are already given, and I shall be glad if he will discuss them. To make the matter definite, I invite him to discuss the trichromatic explanation which I have given, in my first letter, of the case of so-called red-blindness with shortening of the spectrum at the red end. The proof is fully given. Another proof, fully given in geometrical terms, is that dealing with the possible diminution of colour sensitiveness by the annulment of one component sensation.

Instead of discussing any of the eight explanations which I have already given either in full or in outline, Dr. Edridge-Green now points out that he is not alone in regarding the trichromatic theory as inadequate. Unfortunately, misunderstanding of the theory is too regrettably widespread for the reason which I expressed in my first letter. If any reader who is interested in the matter will refer to the discussion which I have given in my book he may recognise that the statement referred to in Dr. Edridge-Green's last letter, concerning contrast and colour blindness, is not correct. It cannot be discussed in the scope of a short letter.

I appreciate Prof. Frank Allen's work greatly. The difficulty to which he refers vanishes, as I am sure he will readily recognise, when the three variables (threshold values) descriptive of non-external action are considered. In fact, in the whole field of contrast, after-images, recurrent images, and inhibition, the trichromatic theory has at its disposal a *double* set, not a single set, of three variables. Such work as that of Prof. Frank Allen is of great importance in view of the need of a formulation of the threshold values as functions of precedent illumination, time, secondary stimuli, etc. His early work, long ago, led me, in attempting something different, to full recognition of the sufficiency of the trichromatic theory.

What blindness must have oppressed the mental vision of Helmholtz, "that investigator, worthy of wonder, leaping before his time," if it were true, as Dr. Edridge-Green asserts, that "There is no fact that directly supports the trichromatic theory." Which Helmholtz elaborated so as to fit facts, and used victoriously to predict others! I know of none that fails to support it. I have studied Dr. Edridge-Green's book very carefully, and I have not found one of his strictures upon the theory with which it was possible to agree. Even Sir William Abney, one of the supporters of the theory, whose experimental work was so admirable, was led to some wrong conclusions through non-perception of some of its possibilities.

Sexual Physiology.

In Nature of September 1, p. 317, under the heading "Sexual Physiology," a review appeared of the second edition of Dr. Marshall's book "The Physiology of Reproduction." In the course of this notice certain misleading statements are made regarding myself. The reviewer, in referring to the chapter of the work dealing with the subject of the fertilisation of the ovum, states, "The least satisfactory part of the book, both as regards arrangement and subject-matter, is, we think, that contributed by Dr. Cresswell Shearer on fertilisation."

May I point out that I am not the author of this chapter; while I have revised Dr. Marshall's manuscript, and added a number of notes here and there of minor importance, the two sections of which I am the author are clearly indicated in the footnotes, and I think are sufficiently obvious. In regard to that part of the chapter which has called forth the special criticism of the reviewer, "The hereditary effects of fertilisation," I am altogether unresponsible, although I completely agree with many of the opinions expressed by Dr. Marshall in this section. As the whole of this paragraph appears almost unaltered in the old edition, it would seem that your reviewer is by no means as familiar with the original work as he would have us believe.

C. Shearer.

A footnote to Chapter vi., "Fertilisation," states that this has been "Revised, with numerous additions, by Cresswell Shearer." It was assumed, from this, that Dr. Shearer had taken the chapter as it stood in the first edition and had made himself responsible not only for the numerous additions but also for the whole of the subject-matter of this chapter in the present edition, and for its presentation. That we are not alone in reading this meaning into the footnote is shown by the fact that another reviewer, writing elsewhere, states that "Dr. Cresswell Shearer has written in this edition a most excellent chapter on fertilisation." If Dr. Shearer did revise the chapter, then his objections are but

formal; but it would appear that he did not revise, as we understand the term, but merely read the manuscript, placing also at the service of the author certain discrete sections for possible inclusion. The footnote is misleading.

THE REVIEWER.

Numerical Relations between Fundamental Constants.

IN connexion with the letter from Dr. Ernest Dorsey in NATURE of October 6, p. 505, it may be pointed out that most of the numerical relations which he describes are implied in the statement given in a paper in the Proceedings of the Physical Society of London (vol. 27, p. 425, 1915), that all units derived from e, m, and c can be expressed (with considerable accuracy) in the C.G.S. system in terms of simple integers (2, 3, or 4), powers of 10, q and π. Here q is a pure number, which represents the value of $2\pi e^2/hc$. This constant is the same as that employed in Sommerfeld's papers on the fine structure of spectrum lines, where it is denoted by α. If the relation of Lewis and Adams (*Phys. Rev.* vol. 3, p. 92, 1914) be accepted, the numerical value of q or α is $(15/\pi^2)^{\frac{1}{3}}/(4\pi)^2 = 7{\cdot}28077 \times 10^{-3}$.

Whether this be the correct value or not, the number represents one of the most important physical constants, and corresponds to a deep-seated relation between the ultimate nature of electric force and that of magnetic force. The quantum theory indicates the existence of discrete magnetic tubes of induction determined by the fundamental unit (h/e), and it has been suggested to me by Mr. W. H. Watson, of the University of Edinburgh, that the constant may be interpreted as giving the relation between a quantum magnetic tube and a unit electrostatic tube of force.

As regards the occurrence of integral powers of 10 in the expressions for physical constants, it must be remembered that the units of length, mass, and time in the C.G.S. system are not entirely arbitrary. The assumption is made that the gram is the mass of 1 c.c. of water at the temperature at which its density is a maximum, and the fact that the "molecular number" (Trans. Chem. Soc. vol. 113, p. 389, 1918) of water is 10 possibly accounts for the relations concerned. Dr. Dorsey includes the gas constant in his list, and here again the physical properties of water are involved through the definition of the Centigrade scale of temperature.

Insects in Korean Amber.

ON the morning of September 1 I saw a piece of carved amber, containing Diptera of several species, in the shop of G. M. T. De Silva in Yokohama. I was informed that it came from Korea (Chosen), but as the exact locality and geological horizon were unknown, and the price was rather high, I did not purchase it. At noon of the same day the earthquake occurred, resulting in the destruction of the whole of Yokohama, including De Silva's shop. I should be greatly interested to learn anything more about this Korean amber, the insects in which should be described. Some days earlier I saw in Mr. Y. Nawa's museum at Gifu a very fine lot of fossil insects, apparently of late Tertiary age. These have never been critically studied or described, but it is to be hoped that they will eventually be properly recorded. I could not discuss them with Mr. Nawa, as he knows no English, and no interpreter could be found at the time of my visit.

Tidal Dissipation of Energy.

IF g denote the intensity of surface gravity, ρ the density of water, and h the elevation of the water surface above its mean position, the potential energy of the oceanic tide is $\frac{1}{2}g\rho h^2$ per unit area. The kinetic energy must be comparable. If h has the equilibrium amplitude of 35 cm., the total energy of the ocean, the area of which is $3{\cdot}7 \times 10^{18}$ cm.^{2}, must be about $2{\cdot}2 \times 10^{24}$ ergs.

Now the mean rate of dissipation of energy by tidal friction is about $1{\cdot}4 \times 10^{19}$ ergs/sec. Thus the whole energy of the tides would be dissipated in about $1{\cdot}6 \times 10^5$ sec., or two days, if dissipation continued at its average rate and no new energy was supplied.

It follows that tidal friction in shallow seas must absorb so much of the energy in the tidal waves that reach these seas, that the lags of the tides in the open ocean may differ by some hours from those calculated on the usual assumption that the coasts may be treated as simple reflecting boundaries.

HAROLD JEFFREYS.

St. John's College, Cambridge.

Repellents of Clothes Moths.

IN NATURE of September 8, p. 376, appears a report of a lecture on "Plants in Relation to the Health of Man," in which Dr. A. W. Hill refers to the supposed property of camphor as a preservative of clothing against moth. Henri Fabre found camphor and naphthalene to have no effect upon moths, and I have found these insects utterly indifferent to such odoriferous substances. In fact, I doubt if they can smell at all. It would be interesting to hear of some definite experimental result bearing upon this point.

REGINALD G. JOHNSTON.

51 Belmont Hill, London, S.E.13.

SOMEWHAT surprisingly, no precise experiments with the object of discovering effective repellents of clothes moths, of which at least three distinct species occur in this country, appear to have been carried out by any one. Mr. R. G. Johnston is perfectly correct in regarding as devoid of any real foundation the popular belief in the efficacy of camphor as a preservative of clothing against moth, although there is no reason for supposing the insects in question to be deficient in olfactory sense. Naphthalene again, if merely scattered loosely in a drawer or wardrobe containing clothes, will certainly afford no protection whatever. On the other hand, naphthalene is quite satisfactory as a repellent if placed inside clothing which is afforded the additional protection of a wrapping of stout paper, the edges of which freely overlap, and are tightly secured by means of pins.

E. E. A.

Amanita muscaria on Hampstead Heath.

THE difficulty of obtaining a supply of this mushroom for scientific investigation is well known to physiologists and chemists. Its disappearance, except in unfrequented woods, is probably accounted for by its attractive colouring and its subsequent destruction as one of the most poisonous representatives of its family. Therefore its occurrence near London deserves to be put on record. A fine specimen, weighing 140 gm. and measuring 12 cm. in diameter, was brought to me for identification by Mr. H. C. Simmons, who found it, after the heavy rains of last week, on the West Heath in the low-lying ground between the North End and Spaniard's Roads.

Boskop Remains from the South-east African Coast.

By Prof. RAYMOND A. DART, University of the Witwatersrand, Johannesburg, South Africa.

THE controversy raging over the Piltdown remains, and the coming of the War shortly afterwards, were the two events which conspired to distract the attention of the scientific world from the significant discovery which was made in South Africa in 1913,

FIG. 1.—External view of the right parieto-occipital fragment of *Homo capensis*, showing the lambdoidal and sagittal sutures.

when a farmer unearthed some fragments of a human skull at Boskop near Potchefstroom in the Transvaal. Last year, the discovery of a more primitive human race in *Homo rhodesiensis* has served to redirect attention to the part which Africa still has to play in elucidating the wider questions of human origins and human migrations.

Since the time the bet between the two farmers as to the "humanity" of the Boskop remains was settled, Mr. FitzSimons, Director of the Port Elizabeth Museum, has been assiduously excavating the rock shelters in that neighbourhood. In June last he forwarded to the Department of Anatomy in the University of the Witwatersrand a consignment of skeletal material which contained the remains of several members of the ichthyophagous Strandlooper race which preceded the Hottentots along the coastal areas.

The Strandloopers, now extinct as a race, were the builders of gigantic kitchen-middens in South Africa. In the particular rock-shelter at Tzitzikama explored by Mr. FitzSimons, this material, in which the Strandloopers had been interred, was removed layer by layer to a depth of fifteen feet. At this level he came upon bones of an entirely different calibre and appearance. Recognising this fact and appreciating the possibilities of the discovery, he forwarded these specimens separately. Altogether, I have received remains of some five individuals from this site, and though mixed together and fragmentary they afford definite evidence that they belong to the same race as was found in the Transvaal in 1913.

Figs. 1 and 2, which illustrate the outside and inside views of part of the right parietal and occipital bones, demonstrate the thickness and texture of the cranial bones in this race. Fortunately, the fragment crosses the line of the sagittal suture (Fig. 1), hence the cranial form is accurately known. It reveals the same type of breadth, flattening, and central depression in *norma occipitalis* that was pointed out for Boskop man by S. H. Haughton.[1]

Fig. 3 shows the inner aspect of three other pieces which were found to articulate exactly along the line of fracture. The state of preservation and general appearance of the bones justifies the assumption that they form part of the left half of the cranium represented by our right parieto-occipital fragment. Fig. 4 is an external view of the same three bony pieces on a rough reconstruction of the endocranial cavity which errs, as I have since determined, on the side of generosity in volume.

So far as the evidence goes, the skull appears to be that of a woman; for other specimens (which I believe to be male) show a more marked glabella, more robust eyebrow ridges, and a greater development of the frontal lobes of the brain. The smallness of the mastoid process, the thickened and tuberculated inferior margin of the tympanic plate, and the very vertical forehead also corroborate its feminine character.

When the fragments have been oriented, the following provisional measurements are obtained: maximal length 210 mm., and maximal breadth 150 mm., as

FIG. 2.—Internal view of the right parieto-occipital fragment of *Homo capensis*, showing the thickness and texture of the cranial bones.

compared with the length of 205 mm. and breadth of 154 mm. secured for the Boskop calvaria. If this length be correctly determined, we are in the presence of the longest-headed human skull yet discovered. It was undoubtedly dolichocephalic.

The first estimations of its endocranial content seemed to show, on account of the extraordinary length, a figure even higher than that secured by

[1] "Preliminary note on the ancient human skull remains from the Transvaal." Trans. of the Roy. Soc. of S.A. Vol. vi. Pt. I. 1917.

Haughton (1832 cubic centimetres), and by Broom[2] (1960 cubic centimetres) for the Transvaal specimen; but after taking casts from the fragments and reconstructing the endocranial cavity, my endocranial cast gives a far smaller capacity—in the vicinity of 1750 cubic centimetres. This figure still reveals a capacity far in advance of the average for modern European brains (Meckel's brain capacity was only 1320 cubic centimetres and Raphael's 1420 cubic centimetres), and is the more striking when it is remembered that the skull is female. The other male crania indicate a greater capacity.

Concerning the Boskop endocranial cast Elliot Smith said, "Its features present a curious blend of those characters which are regarded as distinctive of Mousterian and Aurignacian types of men respectively; but whereas the general form presents certain resemblances to the former, in all essential respects the cast conforms to the type represented by the Cro-magnon man of Western Europe." Broom (*loc. cit.*) goes further and believes it not unlikely that the Boskop type was ancestral to both Neanderthal and Cro-magnon man.

Unfortunately, insufficient jaw remains exist to prove or disprove Broom's contention concerning the supposed massive mandible and large canines. On the whole, the delicacy of the facial skeleton of this specimen is in strong contrast with the massive build and thickness of the calvaria, and scarcely favours the expectation of massive jaws. On the other hand, the nasal process of the maxilla is relatively enlarged and plays an enhanced rôle in bounding the nasal aperture and wall—features emphasised by Boule ("Les Hommes fossiles") as indicating the *ultra-human*

FIG. 3.—Internal view of the three fragments of the left side of the skull of *Homo capensis*. The vascular arrangements are particularly well-marked.

character of Neanderthal man. The pithecoid nature of the small mastoid process, supra-mastoid ridge, mandibular fossa, and superciliary ridges in this type, features which once more link it to primitive Neanderthaloid forms, were emphasised by Haughton (*loc. cit.*). The same point of view is favoured by the relatively low development of the frontal lobes of the brain.

The endocranial cast of this specimen reveals further an extremely broad and depressed Sylvian fossa. The cast is sufficiently complete in this region to show that here the Sylvian depression was even wider and more patent than in the endocranial cast of the Mousterian man of La Chapelle, concerning whom Boule does not hesitate to say that the island of Reil was partially exposed. It seems that, in this respect, our Boskop woman was even more pithecoid. The sulcus lunatus also is prominently indicated in the right parieto-occipital fragment. Incidentally, it may be stated

FIG. 4.—External view of the three fragments of the left side of the skull of *Homo capensis* on a rough preliminary reconstruction of the endocranial cavity. Features to be noted are referred to in the text.

that the endocranial cast indicates a marked asymmetry of brain and skull, the right frontal pole and left occipital pole respectively being more expanded than their fellows of the opposite side.

While certain of the foregoing data betray primitive, if not even Neanderthaloid, features, the study of other skeletal remains favours the Cro-magnon affiliation. A complete femur (also apparently female) indicates by its length (461 mm.) a stature in the vicinity of 5 feet 6 inches, which is considerably above that of Neanderthal man; and the male stature was presumably more considerable. Its straightness and slender build (despite a tendency to the exhibition of a third trochanter, a fossa hypotrochanterica, and a high pilastric index) are also in strong contrast with that of Neanderthal man. The vertebral column in a male specimen in the lumbar region (3rd, 4th, and 5th vertebræ) gives a general lumbar index of 97·4, which indicates a marked lumbar curve (kyrtorhachism) such as is found in modern Europeans.

The more detailed study of the remains may throw clearer light upon a bizarre mingling of characteristics which, at the present time, is highly confusing. It may prove justifiable, as Broom is already convinced, to separate this human group from both Neanderthal and Cro-magnon man as a separate species (*Homo capensis*). There is no doubt, meantime, that these new human documents, which have been brought to light through the energy and enthusiasm of Mr. FitzSimons, have further emphasised the anthropological wealth of Africa, and the need for more cautious investigation of the deeper strata of our coastal rock shelters, with

[2] "The evidence afforded by the Boskop skull of a new species of primitive man (*Homo capensis*)." Anthrop. papers of the Amer. Mus. of Nat. Hist. Vol. xxiii., Pt. II. 1918.

the strictest observance of the methods of modern archæology.

Through this discovery we now know definitely that the Boskop race preceded the Strandlooper race historically. They perhaps owed their extinction to the latter, the Solutrian culture of which (so ably examined by Dr. L. Peringuey,[3] the Director of the South African Museum) indicates familiarity with the uses of the bow. We know further that the Boskop specimen was no human freak, but a type representative of a race once widely distributed in South Africa from the Transvaal to the remotest south-eastern corner of the continent.

The implements, culture, and æsthetic achievements of these big-brained men of pre-history still remain to be discovered. Their employment of ochre in their burial rites indicates their familiarity with pigments and the artistic and symbolical uses to which they might be put. The remarkable parallelisms between the so-called "Bushman" art and that of Cro-magnon man in Europe was insisted upon by Sollas many years ago, and the evidence may yet be forthcoming which will conclusively solve the fascinating yet elusive problem of their correlation.

Insulin and its Value in Medicine.[1]

By Prof. J. J. R. MACLEOD, F.R.S.

CARBOHYDRATES are essential in the chemical processes upon which life depends. Not only is the glucose, the form in which they are mainly absorbed into the blood, the source of muscular energy, but it is also in some way necessary in the oxidation of fats. Preceding its oxidation, glucose undergoes a series of preliminary changes which proceed step by step in such a manner that a long series of intermediary substances is formed; and when anything interferes with the process at any stage, as in diabetes, glucose accumulates in the blood and tissue fluids, causing the main early symptoms of the disease, hyperglycæmia and glycosuria. Later involvement of the oxidation of fats results in the accumulation of the ketone bodies in the organism, and these, by their toxic action, cause the often fatal condition of coma.

The control of this process of carbohydrate metabolism has for years been assumed to be the function of a hormone derived from the Isles of Langerhans of the pancreas. Although the existence of this hormone was fairly certain, little success resulted from attempts to extract it in potent form from the pancreas, probably because it was destroyed by the powerful digestive enzymes also present in such extracts. Banting and Best circumvented these by making extracts of the degenerated residue of pancreas following ligation of the ducts, it having previously been shown that in this residue the islet cells are more or less intact but the external secretory cells are largely degenerated. The extracts were found to remove the two chief symptoms of diabetes in depancreatised dogs. Alcoholic extracts of adult beef pancreas were also found to contain the hormone, and by their continued use it was possible considerably to prolong the life of the diabetic animals. J. B. Collip then succeeded by fractional precipitation with alcohol in ridding these alcoholic extracts of irritating substances, so that they could be repeatedly injected into diabetic patients.

With larger supplies of insulin available, it was now possible to show that it removes all of the observable symptoms of diabetes in depancreatised dogs. Thus, not only did it cause glycogen to become deposited in large quantities in the liver when sugar was fed to the animals, the first analysis giving more than 20 per cent. of this substance (J.B.C.), whereas without insulin traces only are found, but it also caused the respiratory quotient (ratio between CO_2 and O_2 in respired air) to become raised. These results were soon confirmed on diabetic patients. In more recent work, in which depancreatised dogs were given insulin daily along with considerable quantities of carbohydrate, life has been prolonged for over four months, and by careful comparison of the sugar balance of the animals it has been found, by F. N. Allen, that a small amount of insulin is capable of causing relatively much more glucose to be metabolised than when a large amount is given. Or, in other words, the glucose equivalent per unit of insulin is much higher with small than with large doses.

Although there can be no doubt of the high therapeutic value of insulin in the treatment of many cases of diabetes, its value as a new instrument for the investigation of problems of metabolism other than those relating to this disease is also high. Evidence for this belief is founded, among other things, on the striking effects of insulin on normal animals. When it is administered to rabbits, for example, the first effect is a very rapid lowering in the percentage of sugar of the blood—first observed by J. B. Collip—and when this reaches a certain level symptoms of a peculiar nature supervene. These consist usually of violent convulsive seizures each lasting for a minute or so, and of a gradually increasing state of coma, with fall in body temperature, ending often in death from respiratory failure. Symptoms of a similar character occur also in other animals, including man, after large doses of insulin.

The symptoms were found to be dependent on the lowering of blood sugar; thus, they usually supervene in normally fed animals when the blood sugar has fallen to about 0·045 per cent., and they are removed immediately by the addition of glucose to the blood either by administering this sugar subcutaneously or by causing it to be liberated in the body from glycogen, as by the injection of adrenalin (epinephrin). It was found, moreover, that, of all the sugars, glucose alone has an immediate and lasting effect, even leavulose and galactose, which are its nearest neighbours, having only a slight and transitory action.

Although the symptoms commonly occur in well-fed

[1] A lecture delivered in the Section of Physiology of the British Association at Liverpool on September 17.

animals when the blood sugar is about 0·045 per cent., they may fail to be observed until a much lower level has been reached. This is particularly the case when a large dose of insulin is given some time after food. The liability of symptoms to occur at the above percentage of blood sugar has served as a useful basis for measurement of the dosage of insulin, one unit being defined as the amount which can lower the blood sugar to the convulsive level of 0·045 per cent. within four hours in rabbits weighing about 2 kilogrammes. Since this "physiological" unit, as it is called, is said to be stronger than is necessary for certain clinical purposes, it has been decided for the present to use, as the "clinical" unit, one that is one-third the above strength. This question of the physiological assay of insulin is receiving much attention at present.

These observations clearly pointed the way to the next problem, namely, the cause for the lowering of blood sugar. At first it seemed as if this should soon be solved, for, as already mentioned, it has been found that insulin not only causes glycogen to be deposited in the liver of diabetic animals, when sugar is given, but also causes the respiratory quotient to become raised in a manner to indicate that there is increased combustion of carbohydrate. It seemed likely that stimulation of the same processes in the normal animal under insulin must be responsible for the disappearance of glucose from the blood. But the experimental evidence goes to show that the mechanism of action is much more complex. It has recently been found that glycogen is not formed when insulin is given along with sugar to normal animals (McCormick, O'Brien, and E. C. Noble); indeed, when given to those that are well fed it is decreased in amount (Dudley and Marriam), and no certain evidence can be obtained from respiratory experiments that more active combustion of glucose is a necessary accompaniment of the lowering of blood sugar. The consumption of oxygen greatly increases in dogs preceding the onset of symptoms, and the respiratory quotient usually becomes somewhat raised (Dixon, Eadie, and Pember), but in mice changes of an opposite character occur (Dudley, Laidlaw, Trevan, and Boock); in rabbits the symptoms are at first like those in dogs, though less marked, and subsequently like those in mice.

The glucose which disappears is apparently neither oxidised to carbon dioxide and water nor polymerised into glycogen. For the present the problem is unsolved, but we must not lose sight of the possibility that insulin changes both glucose and glycogen into some intermediary product which we fail to identify with our present methods of analysis, either because it does not give the reducing reactions upon which the detection and estimation of sugars depend, or because it is not precipitated by alcohol after treatment with strong alkali, which is the characteristic property of glycogen. That such substances may exist in the tissues is indicated by the fact that it is impossible after injecting large amounts of sugar into animals to recover much more than one-half by chemical analysis of the entire body.

Whatever may be the nature of the mechanism by which the blood sugar becomes lowered, there is no doubt that it acts in the tissues and not in the blood itself (Eadie). Thus, the addition of insulin to blood incubated outside the body does not alter the rate at which the sugar disappears from it, and when the isolated heart is perfused with a suitable saline solution containing sugar the addition of insulin to the solution causes this to lose its sugar more rapidly (Hepburn and Latchford). The hypoglycæmic effect of insulin lasts for a period which varies in different animals. In rabbits the blood sugar often begins to rise again in about an hour after the injection, but this depends very largely on the amount of glycogen which is stored in the liver. This becomes converted into glucose to replace that lost from the blood, so that well-fed animals show much quicker recovery and can withstand much larger doses of insulin, without the development of symptoms, than those previously starved. This mobilisation of the carbohydrate reserves would appear to depend on the transmission to the liver through its nerve supply of messages set up by the hypoglycæmic condition, for Burn has shown that if the nerve pathway (splanchnic) be locked by the drug ergotonine, insulin causes, in well-fed animals, a more profound degree of hypoglycæmia than otherwise.

Another important effect of insulin is on the hyperglycæmia due to other causes than removal of the pancreas. So far as it has been investigated, insulin is capable of preventing the development of hyperglycæmia in all these conditions. Most attention has been paid to its effect on the hyperglycæmia due to epinephrin, partly because of the possibility that insulin may be assayed by determining the amount necessary to antidote a known amount of epinephrin, which itself can be accurately assayed, and partly because an investigation of the physiological antagonism between these two hormones may throw some light on the mechanism of the action of insulin. One example may be given to illustrate this. We have seen that insulin causes the glycogen stored in the liver to become less in amount, acting in this regard like epinephrin, although probably much less quickly. When insulin is given along with epinephrin, however, glycogen disappears from the liver much more slowly than with epinephrin alone, indicating that under certain conditions the pancreatic hormone arrests rather than stimulates the breakdown of glycogen. When these two hormones are in excess in the body, one prevents the other from causing glycogen to disappear. Another curious result of a somewhat similar nature has been obtained by Burn with pituitrin, a hormone derived from the pituitary gland. When it is given along with epinephrin it also prevents hyperglycæmia, and when it is given with insulin it prevents hypoglycæmia. These results indicate the very puzzling nature of the problem of the action of insulin, and they show that this action may possibly be linked with that of other hormones in the animal.

Chemically, insulin usually gives the biuret test, and it behaves in its general properties not unlike a proteose. It may, however, be a much simpler substance, since active preparations have been obtained from the pancreas of the skate, in which no biuret test could be obtained. Its chemical identity being unknown, it is of course out of the question that it could at present be prepared synthetically.

The Origin of Petroleum.

UNLIKE most problems concerning origins, which have but a philosophic or academic interest, that of the genesis of petroleum has a distinctly practical significance, for if solved, prospectors for mineral oil would be provided with important data and chemists might learn how to produce artificially valuable substances similar to, if not identical with, natural petroleum. Man's fertile imagination has spun not only an embarrassing number of speculations and hypotheses concerning the nature of the raw material or materials from which petroleum has been derived, but also innumerable explanations of the *modus operandi* of its formation. Of these, only a tithe remains. Explanations that affirm a cosmic origin or postulate volcanic activity as the effective cause, have long been abandoned, and to-day there are only three which find scientific support. The least popular of these, the inorganic theory, affirms that petroleum originates from the interaction of metallic carbides, presumed to exist immediately below the earth's outer crust, and steam, whereby various hydrocarbons are formed, and these undergo further changes, including polymerisation, to produce the compounds that are found in petroleum. It has recently been suggested that the methane synthesis from carbon monoxide or dioxide and hydrogen, in the presence of a catalyst, such as vanadium or nickel, of which traces are found in petroleum, might also explain the initial formation of hydrocarbons in Nature, and the presence of methane in natural gas; but these suggestions fail to interpret the occurrence of optically-active substances in petroleum, and the presence of nitrogen in some oils, while geologists have met them with uncompromising hostility.

The views that are uppermost to-day are that petroleum is derived from either animal or vegetable substances, or from both of these sources, and the chief direct evidence supporting this organic theory is the occurrence in petroliferous strata of vegetable and animal remains, including, in a few cases, remains of bacteria. Important, if less direct, testimony is the presence in petroleum of the optically-active substances cholesterol and phytosterol, which are characteristic constituents of animals and plants, respectively. The various elaborations of this view are mainly concerned with the nature of the chemical reactions involved, and how they are influenced by the three determining factors of pressure, temperature, and time; it is, however, not easy to formulate any one hypothesis to explain the formation of such complex mixtures as mineral oils, and still more difficult to account for the great diversity in chemical composition exhibited by mineral oils from different localities.

The evidence admitted by those who believe in a purely animal origin includes the statements: that petroleum found in primary rocks is much more often accompanied by animal than by vegetable remains; that formations containing only plants are not bituminous; that mixtures of hydrocarbons similar to those found in petroleums can be made artificially from animal fats, and that such production can be observed in Nature to-day, notably in the coral reefs and lagoons of Djebel Zeit in Egypt. The scarcity of animal fossils in petroliferous strata is explained by assuming that the fauna were either skeletonless, or, if not, their calcareous coatings were dissolved by the carbon dioxide liberated during their decomposition. Advocates of the vegetable origin doubt if the supply of animal matter has been sufficient for the purpose, plants being much more plentiful than animals; they comment on the absence of phosphatic deposits from the vicinity of oilfields; and many trace relationships between coals and petroleum.

Mr. E. H. Cunningham-Craig is one of the foremost supporters of the purely vegetable theory, and in opening the discussion on the origin of petroleum, held by the Institution of Petroleum Technologists in London on October 9, he brought forward evidence in its favour derived from recent researches. Geological evidence is accumulating in support of the view that coals and lignites are related to petroleum. Thus, in Trinidad, the three main oil-bearing horizons have each a carbonaceous phase in some other district, and the petroliferous and carbonaceous phases approach each other very closely in some localities. Similar evidence is found in Venezuela, Burma, Assam, Hungary, and Rumania. The D'Arcy well, near Dalkeith, was drilled on the assumption that oil-shale deposits represent petroleum that is "dead and buried," and therefore that free petroleum might be found beneath the oil-shale series; actually it was discovered below the oil-shale at each of two predicted depths. Dr. F. Bergius, of Heidelberg, has hydrogenised coal by heating it in free hydrogen in an autoclave at very high pressures and at temperatures up to 455° C. As the result of an exothermic reaction, a liquid was obtained that was "almost identical with crude petroleum." The determining factors of the formation were the proportion of volatile matter in the coal and the pressure. Nature, it is thought, may act in a similar way, but more slowly and at lower temperatures, on vegetable matter before it has reached the coal stage, *i.e.* while it still contains much hydrogen in proportion to carbon.

Supporters of the animal theory, said Mr. Cunningham-Craig, should endeavour to repeat Dr. Bergius's experiments with animal matter in place of vegetable. Cannel coals yield most oil on distillation; they contain much inorganic matter and are not highly carbonised. Torbanites also give high yields of oil and are to be regarded as cannels containing colloidal inorganic matter which has been heated in a natural autoclave. In this process it is assumed that the oil liberated from the torbanite combines with the colloidal inorganic matter to form the gels that can be seen in the microscope; but the conversion into petroleum has not been complete owing to partial carbonisation. Prof. A. E. Flynn has separated and investigated the gels occurring in torbanite from Nova Scotia, and has proved conclusively that they are not vegetable fossils; so that if oil-shale is petroleum "dead or buried," torbanite is petroleum "still-born."

Mr. Cunningham-Craig's paper met with many criticisms, both from the chemists, led by Dr. A. E. Dunstan, and from the geologists, led by Mr. Dewhurst. Dr. Dunstan raised obstacles to more than one theory; for example, he cannot admit that the laboratory methods of producing hydrocarbons from fatty acids

are applicable in Nature, and it is difficult to see why the molecules of such acids occurring in natural fats and containing even numbers of carbon atoms should give rise to molecules present in petroleum which contain both odd and even numbers of carbon atoms. He has analysed many times the liquids obtained from coal by the Bergius method, and has found that their similarity to petroleum is very remote. How can the presence of benzene, toluene, and xylene in certain petroleums be explained? Is it not probable that there are several modes of origin? Light is required on the origin of the vast amounts of methane present in natural gas. What happens to the nitrogen and phosphorus contained in animal organisms? Why is iodine so scarce in petroleum? Mr. Dewhurst said that petroleum found in the Upper Silurian was much earlier than the earliest vegetation, and earlier than the coal found in the Late Devonian. Palæozoic oil was probably formed from any organic matter available, and there were two distinct types of oilfield: the lignitic, of vegetable origin, which was deposited in areas where the climate was moist, and oilfields of marine animal origin, which are found associated with deposits of salt, gypsum, etc., and were formed in deltas that were cut off later from the mainland.

The discussion generally was suggestive and served its purpose in crystallising thought around important nuclei. If it did not bring nearer a definitive solution of the problem, it at least showed how far we have progressed since the time when a Polish cleric, named Kluk, traced the origin of petroleum to the Garden of Eden, which was so fertile that it must have contained fats; at the Fall this fat partly volatilised and partly sank into the earth, where it was finally transformed into mineral oil by the changes induced by the Flood. Truly, a science progresses by changing its points of view.

Obituary.

Dr. Herbert McLeod, F.R.S.

Dr. HERBERT McLEOD, who died on October 3, was born at Stoke Newington on February 9, 1841, and was the son of Mr. Bentley McLeod. He was educated at Stockwell Grammar School. In 1860 he became lecture assistant to Prof. A. W. Hofmann at the Royal College of Chemistry. Former students of this College never forget the brilliant way in which McLeod carried out the experiments shown at the lectures. Hofmann was so impressed by his ability that he arranged that, in addition to acting as his assistant, McLeod should take the entire College curriculum. He worked with Hofmann on aniline dyes and had a part in the discovery of magenta. McLeod accompanied Hofmann to Berlin. A little later he returned to the Royal College of Chemistry as assistant to Prof. Frankland. At this period he published papers on acetylene, on a new form of aspirator, and, in conjunction with Frankland, a Report to the British Association on the determination of the gases in well-waters.

In 1871 McLeod was appointed professor of experimental science (afterwards chemistry) at the Royal Indian Engineering College, Cooper's Hill. He held this post till 1901. In 1876 he published a description of "An Apparatus for Measurement of Low Pressures of Gases." The McLeod gauge described in this paper is now commonly used. A little later, in 1878, McLeod published, in conjunction with G. S. Clarke (now Lord Sydenham), a paper on "Some Figures exhibiting the Motion of Vibrating Bodies and on a new Method for Determining the Speed of Machines." The method, developed in this and in later papers on the subject, has since led to most important applications. He devised a sunshine recorder and took a keen interest in meteorology, making daily observations at 9 A.M. and 3 P.M. over a period of twenty years.

A visit paid by the late Lord Salisbury to the Royal College of Science led him to invite McLeod to co-operate with him in scientific experiments. Week-end visits to Hatfield House were frequent until Lord Salisbury became Prime Minister. Some account of these experiments was given in the obituary notice of Lord Salisbury which McLeod wrote for the Royal Society.

From 1888 onwards McLeod had been reading proofs of the Royal Society's Catalogue of Scientific Papers. After the death of Mr. George Griffith in May 1902, McLeod undertook the direction of this Catalogue. His chief work upon the Catalogue was the preparation of a subject-index to all scientific papers published between 1800 and 1900. All the index slips necessary for this work were prepared under his direction, and the volumes for mathematics, mechanics, and physics were published. The author Catalogue for 1883–1900 was also under his charge, and he had seen half of this through the press when, in 1915, he was obliged, through ill-health, to give up active work.

McLeod was honorary LL.D. of St. Andrews, was elected a fellow of the Royal Society in 1881, and was president of the Chemical Section of the British Association at Edinburgh in 1892. He became a fellow of the Chemical Society in 1868 and served on its council in 1871–74, and again 1880–84. He was vice-president of the Chemical Society in 1887–90, and again 1901–4. He served on the Council of the Royal Society in 1887–89.

Dr. Arthur A. Rambaut, F.R.S.

Arthur Alcock Rambaut, Radcliffe Observer at Oxford, who died at a nursing home on October 14, after a prolonged illness, was born at Waterford on September 21, 1859, and was a son of the Rev. E. F. Rambaut. At Trinity College, Dublin, he won a first science scholarship in 1880 and took his degree the following year as senior moderator and gold medallist in mathematics and mathematical physics. Having spent some time as senior science master at the Royal School, Armagh (where he had been educated himself), he was in 1882 appointed assistant at the Dublin University Observatory at Dunsink under Sir Robert Ball. He had charge of the transit circle and observed regularly with it for about eight years, the results being published in Parts VI. and VII. of the "Astronomical Observations and Researches made at Dunsink." This work was laid aside when Mr. Isaac Roberts presented the observatory with a 15-inch reflector, with which some of his earliest work in astronomical photography had been made. Rambaut

commenced work with this instrument as soon as the clockwork had been somewhat improved, and a photographic survey was made of the great star cluster in Perseus and published in a paper by Ball and Rambaut in the Trans. R. Irish Academy. Soon after, in the autumn of 1892, Ball left for Cambridge and Rambaut was appointed to succeed him as Andrews professor of astronomy and Royal Astronomer of Ireland. During the next five years he continued his photographic work, but under great difficulties and with long interruptions, as the mounting, clockwork, and the dome under which the instrument was housed were all found to be useless and had to be replaced by others.

In 1897 Rambaut left Dunsink to take up the post of Radcliffe Observer at Oxford. Up to that time the Radcliffe Observatory had been devoted almost altogether to meridian work, and the observations made since 1839 had been regularly published. But a vast number of observations made in the years 1774 to 1838 had never been prepared for publication, and Rambaut spent a good deal of time examining them. He showed that they had been carefully made and would be worth printing, but he did not succeed in obtaining the necessary means for reducing and printing these old observations. In the meantime the Radcliffe Trustees decided to procure a first-class instrument for astronomical photography, and a tower was built in the grounds of the observatory, surmounted by a dome 32 feet in diameter. In this was, in 1902, erected a photographic instrument by Sir Howard Grubb, consisting of a photographic refractor of 24 inches aperture and an 18-inch refractor for visual work. In 1904 stellar parallax work was commenced, arranged according to the programme proposed by Kapteyn and in consultation with him, and this work has been continued ever since. A volume of the Radcliffe Observations published about a month ago contains the resulting parallaxes of 2400 stars in addition to full descriptions of the instrument and measuring apparatus.

More than a year ago Rambaut was attacked by illness, from which he never recovered. It was therefore very fortunate that the chief work of his life had been completed. He will be much missed by the many friends his cheerful and kindly disposition had won for him at Oxford. He leaves a widow and three sons to mourn his loss. J. L. E. D.

Dr. J. A. Harker, O.B.E., F.R.S.

John Allen Harker was born at Alston, Cumberland, on January 23, 1870, and died at Highgate on October 10. He was thus only in his fifty-fourth year at the time of his death. The son of the Rev. John Harker, Congregational minister, he was educated at Stockport Grammar School, thence proceeding to the University of Manchester (Owens College), where he was elected Dalton scholar in chemistry in 1891 and a year later Berkeley fellow in physics, taking his M.Sc. A research course at Tübingen followed, where he took the Ph.D.

Harker spent some little time in France, working with Moissan on electric furnaces, and in collaboration with Chappuis carried out in 1900 a classic comparison of the gas and platinum thermometer scales. About this time the National Physical Laboratory was being brought into being at its first home at Kew Observatory, and Dr. Harker was one of the little band of devoted workers whom Sir Richard Glazebrook gathered round him at the beginning of the great endeavour which resulted in the present institution at Teddington. Harker became chief of the thermometry branch of the Physics Department. His work over a period of the next ten years is largely reflected in a series of valuable papers, mostly on high temperature measurement, for which he received the F.R.S. in 1910. At the International Petroleum Congress at Vienna in 1912 he was the delegate of the British Government. His researches with W. F. Higgins on flash-points of oils enabled him to make valuable contributions to the discussions. In association with the present writer, Dr. Harker subsequently worked on the thermionics of high-temperature furnaces—a subject on which he gave a Friday evening discourse at the Royal Institution. In 1913 he went for several months to Eskdalemuir Observatory as temporary superintendent.

When the War broke out Harker was lent by the National Physical Laboratory to the Inventions Department of the Ministry of Munitions, and became director of the research laboratory and was responsible for the organisation of the work of the Nitrogen Products Committee. In this capacity he visited Canada and the United States in 1918, and was on board the Cunard liner *Andania* when she was torpedoed off northern Ireland. On that occasion a generous act of self-sacrifice undoubtedly aggravated the ill effects of the exposure on his constitution. Harker also went on similar missions to Norway, Sweden, and France. He received the O.B.E. in recognition of his valuable War services.

After the War, Harker returned to Teddington for a brief period before setting up as a consulting engineer with Dr. J. F. Crowley in Westminster. He was a vice-president of the Faraday Society, and had served on the Council of the Physical Society. He was a prominent member of, among others, the Oxygen Committee and the Gas Cylinders Committee of the Research Department.

Harker was a man of great scientific keenness and a highly strung and very likeable personality, who will be greatly missed by his friends. He possessed a great fund of scientific reminiscences. Though never of robust physique, he did not hesitate to make frequent inroads on his reserve of nervous energy. His devotion to his War duties doubtless served to undermine his constitution, and at the end his illness was only short in duration. He married Ada, the daughter of the late Thomas Richardson, of Alston, and had two sons and three daughters. The cremation took place at Golders Green on Saturday, October 13. Among those present were Sir Richard Glazebrook and Sir Robert Robertson. Dr. T. E. Stanton represented the Royal Society and Dr. E. Griffiths and Mr. F. H. Schofield the Director and staff of the National Physical Laboratory. G. W. C. Kaye.

We regret to announce the following deaths:

Rev. H. J. Bidder, a curator of the Botanic Garden, Oxford, on October 19, aged seventy-six.

Mr. R. A. P. Rogers, Donegal lecturer in Trinity College, Dublin, on October 17.

Current Topics and Events.

SPAHLINGER'S consumption cure is once more brought to public notice, and, at the invitation of Baron Henri de Rothschild, Mr. Spahlinger met a number of medical men at the Ritz Hotel in London last week. In an article in NATURE, April 7, p. 453, we published the main facts, so far as they were known, of Spahlinger's consumption cure. His claims were shown to rest on a series of categoric statements of which we still await scientific proof. In some mysterious way, however, the subject recurs like the seasons, and yet we get no further. We are now informed that he cannot produce the "goods" because the Spahlinger family fortune to the extent of 80,000*l*. has been spent in the experiments, and therefore more will be required before the public can taste the benefit. When it is remembered that such a sum would nearly maintain the Rockefeller Institute in New York for a year, it is difficult to understand why the result is so meagre. The object of the meeting in London was to produce a pamphlet which would give the history of Spahlinger's work, particulars of papers which have been read, and clinical histories of the cases hitherto treated. When these works have been in the hands of doctors for a month or six weeks, we are going to hear about the Spahlinger treatment again, we are told, for an appeal will be made to a generous public for money to carry on the work. In these days of scarcity, it would seem advisable to know something about the remedy apart from the claims made on its behalf.

THE statement made by Sir L. Worthington-Evans to the Imperial Economic Conference, on cable communication throughout the Empire, is quite satisfactory. Before the War none of the Atlantic Cables was owned by a British company. Now there are two. The German cable from Emden to New York *via* the Azores has been acquired and diverted, and the cable of the Direct United States Co. has been purchased. The average transmission time for full-rate telegrams between London and Montreal is now about 45 minutes. The other link in the State-owned route to Australia and New Zealand is the Pacific Cable laid in 1902. It is now loaded to its full capacity, and the question of duplicating it is under consideration. In other parts of the world the cables provided by the Eastern Telegraph Co. and its associated companies have proved capable of meeting the demand. These companies and the Pacific Cable Board did invaluable work during the War. Britain, however, has fallen behind other nations in radio communication. America, France, Germany, Japan, and the Argentine have outstripped us. This is due to the apparently interminable negotiations between the Marconi Company and the Government. We have good hopes that with the able help of the Dominion Premiers an agreement will soon be arranged. Lord Burnham suggests that permission be given to private enterprise to operate the stations, the Government reserving the right of purchase after a term of years. Judging, however, from the analogous experiment that was tried when electricity supply companies were first established in Great Britain, we think it very doubtful whether a scheme of this nature would succeed. Several other suggestions have been made, and we sincerely hope in the national interests that this little-creditable dispute will soon be settled.

SINCE Summer Time was first introduced in 1916, many different views have been expressed as to when it should begin and end. Expediency rather than principle seems to have determined these dates, which, in Great Britain, have varied from March 24 to April 8 at the beginning and September 17 to October 25 at the end. There has also been no general agreement between Great Britain and other European countries as to the period during which Summer Time should be in force. Mr. Bridgeman, Home Secretary, told a deputation from the Newcastle Chamber of Commerce on October 19 that he was consulting authorities in France in the hope of arriving at such an agreement. The dates in Great Britain, namely, the day following the third Saturday in April and the day following the third Saturday in September, are laid down by the Summer Time Act, and it will be necessary to repeal or amend this Act in order to extend the period, as urged by the Newcastle deputation. Duration of daylight is, of course, a function of latitude, so that whatever dates are decided upon for the change of time-reckoning must be a compromise as to their effects, even in different parts of Great Britain. During the summer months Newcastle and places north of it do not need Summer Time legislation to give them daylight during all their working hours. On this account, it has been suggested that Greenwich Time should be used near the summer solstice—say in June and July—so that clocks would have to be altered four times a year instead of two. This would, however, increase the confusion already caused by the introduction of Summer Time, and we trust that the change will be limited to two dates a year, whatever they are.

IT is rather interesting to note that among the representatives of the Dominion of Canada at the Imperial Conference now sitting in London, five of them are fellows of the Royal Society of Canada. The Rt. Honourable William Lyon Mackenzie King, Prime Minister, author of several works on political economy; Dr. O. D. Skelton, professor of political economy at Queen's University; Dr. R. H. Coats, Dominion Statistician; Col. A. G. Doughty, Dominion Archivist, are all members of Section II. (History and Literature) of the Royal Society of Canada, whilst Dr. Charles Camsell, who is honorary secretary of the Society, Deputy Minister of Mines, and has under his direction the Geological Survey, the National Museum, and the Mines Branch of the department, is a member of Section IV. (Geological and kindred Sciences). There is also associated with these representatives Dr. J. H. Grisdale, Deputy Minister of Agriculture, also the head of the Experimental Farms of the Dominion, the post formerly

held by a past president of the Royal Society of Canada in the person of the late Dr. W. E. Saunders. It is thus evident that in the fields of literary, historical and scientific research in Canada, the right men were found to represent that portion of the British Empire at the Imperial Conference.

On Tuesday next, October 30, occurs the centenary of the death of Dr. Edmund Cartwright, the inventor of the power loom and other textile machinery. Born in 1743, a few years after Arkwright, his life coincided with the great Industrial Revolution, to which he made notable contributions. Of a good Nottinghamshire family, he was educated at Wakefield Grammar School and at University College, Oxford, and took holy orders. He was given the perpetual curacy of Brampton, near Wakefield, and in 1779 he was appointed to the living of Goadby Marwood, in Leicestershire; it was there he made his first loom. It was during a holiday visit to Derbyshire in 1784 that his attention was directed to the need of a mechanically worked loom, and though he had had no previous experience of mechanics or weaving, with the aid of the village carpenter and smith, he made a rude form of loom which could be worked by other agency than the hands and feet of the weaver. He took out patents, at Doncaster set up a factory, and there produced the earliest samples of power woven goods. At the same time, he turned his mind to the difficult problem of wool-combing by machinery, and here again made a certain amount of advance. His projects, however, proved financial failures, and in 1793 he sold his factory and removed to London. Among his other inventions was an engine to be driven by steam or spirit vapour, in which he applied the practice of surface condensation. He was also known for his experiments in agriculture and for several years worked for the Dukes of Bedford at Woburn. Though the power loom came into use somewhat slowly, by the beginning of the nineteenth century it was becoming common, and in 1809 Cartwright's services to the cotton industry were acknowledged by the grant to him by the Government of a sum of 10,000*l*. A part of this Cartwright spent on the purchase of a farm in Kent, and there he spent the evening of his days, experimenting to the last.

"The Martyr Roll of Science" is the title of a sympathetic article by Mr. Harry Cooper in the *Sunday at Home* for October, in which details are given of the life and work of many of those who have given their lives in the pursuit of knowledge and the service of mankind. No mention is made of the victims of engineering and chemical and physical research, and only a passing reference to those of geographical exploration—Franklin, Scott, and Shackleton—the bulk of the article dealing with the tragic happenings of medical research. Arthur Bacot and H. T. Ricketts were stricken down by typhus fever, and the interesting information is given that a hundred years ago Sir Humphry Davy likewise contracted typhus fever, then so familiar in prisons as to be known as "gaol fever," having visited Newgate in order to devise a disinfectant against the disease, but happily recovered. Yellow fever claimed Jesse Lazear, who allowed himself to be bitten by mosquitoes that had fed on the blood of yellow fever patients. The list of X-ray martyrs is unhappily a long one—Hall-Edwards, Lyster, Clarence Dally, Ironside Bruce, Radiguet, Kassabian, Vaillant, Bergonié, and others. Kala-azar attacked Pirrie, and other names might have been added to Mr. Cooper's roll of honour. Thus trypanosomiasis claimed Tulloch; African tick fever, Dutton; yellow fever, Walter Myers; and typhoid fever, Louis Jenner and Allan Macfadyen. "Such heroisms give the answer to those who imagine Science to be a rigid, emotionless thing, and its devotees to be hard men, forgetful of humanity in their intellectual absorption."

The inaugural lecture of Prof. A. V. Hill in the Anatomy Theatre of the Institute of Medical Sciences at University College on October 16 was a brilliant and inspiring account of the present tendencies of physiological science. Prof. Hill came to physiology from physical science and is thus more favourably situated in regard to his freedom of suggestion and criticism than many biologists of a more restricted training. As present tendencies, he instanced the unparalleled advance in biochemistry during the past few years. It is now difficult to define precisely where physiology ends and biochemistry begins. Day by day the analysis of the whole mechanism of the living organism becomes more refined and elaborate. Prof. Hill cited the brilliant work of Hartridge and Roughton, which has recently brought the study of the time-course of the reactions of hæmoglobin with gases, occupying only a few hundredths of a second, under direct experimental observation. The development of further and finer physical methods of analysis is another tendency, while the old main road of the experimental method remains an essential means to progress in physiology. Direct physiological research on man is developing to the great advantage of medicine and sociology. It is essentially the study of the normal. A fifth tendency is less obvious: the amplification of the field of zoology through the adoption of experimental methods. That may help to correct the analytical tendency. Re-synthesis is necessary and zoology will not forget the animal as a whole. Anatomy, too, will gain as increasingly greater emphasis is placed upon the living structure, and the elucidation of the working of the central nervous system will link up structure with function. Not the least interesting remarks of Prof. Hill were those concerning the spirit of adventure—even a reckless spirit of adventure—in science, without which the most highly organised team work must be sterile and bureaucratic. The adventurer may be wrong, but he "catalyses" his more reasonable brothers.

The Salters' Institute of Industrial Chemistry has awarded sixty-four grants in aid to chemical assistants, occupied in factory or other laboratories in or near London, to facilitate their further studies.

Through the generosity of the late Mrs. E. O Durham, wife of Lieut.-Col. F. R. Durham, chairman of the Junior Institution of Engineers, 1907–1909, that Institution has offered annually a bursary of 25*l*. for competition among its members between the ages of 20 and 23 years. By her will, the Institution is to receive a sum to endow the bursary in perpetuity.

We learn from *Science* that at the annual meeting of the American Chemical Society at Milwaukee on September 12, the Priestley medal, awarded triennially by the society for distinguished services to chemistry, was bestowed on Dr. Ira Remsen, president and emeritus professor of Johns Hopkins University, Baltimore.

The Council of the Institution of Civil Engineers has made the following awards in respect of selected engineering papers published without discussion during the session 1922–1923: A Watt medal to Mr. T. E. Houghton (Liverpool); and Telford premiums to Mr. J. W. Meares (Guildford), Mr. J. W. Spiller (Maidenhead), and Dr. G. S. Coleman (Manchester) and Mr. Dempster Smith (Manchester); and in respect of papers read before meetings of students of the Institution in London and the provinces during the same period,—Miller prizes to Mr. E. L. Everatt (Newcastle), Mr. J. G. Kimber (London), Mr. A. H. Naylor (London), Mr. E. Sykes (Birmingham), and Mr. F. J. Symonds (London).

Applications are invited for the post of an assistant government analyst in Ceylon. Candidates must have had experience in general analytical and bacteriological work and in toxicological analysis, be associates or fellows of the Institute of Chemistry by examination in branch E (chemistry—including microscopy—of food, drugs, and water), and preferably possess an honours degree of a British University. Application forms and further particulars are obtainable from the Assistant Private Secretary (Appointments), Colonial Office, S.W.1.

A movement is on foot to commemorate the late Sir Isaac Bayley Balfour. An area of 50 acres in Glenbranter Forest, Argyllshire, where the plants raised at the Botanic Garden, Edinburgh, can be cultivated under suitable conditions and where trials may be made in the rearing of newly imported conifers and other trees, has been secured for the purpose. It is proposed that the area shall be called the Bayley Balfour Arboretum or Garden, and that the memorial shall take the form of a rest-house for the use of visitors. Subscriptions towards the memorial are solicited. They should be sent to the honorary secretary and treasurer, Mr. J. Sutherland, 25 Drumsheugh Gardens, Edinburgh.

Messrs. Longmans and Co. are publishing shortly vol. 1. of a work on "Cosmology," by Prof. J. O'Neill, of Maynooth, which, it is said, is the first attempt at an English treatise on scholastic cosmology. The study of the text of Aristotle and of St. Thomas has led the author to ascribe to these thinkers views different from those attributed to them in most contemporary manuals. The second volume on "Modern Cosmology" will be published next year; its purpose is to show that scholastic cosmology contains a sounder philosophy of matter than any of its present-day rivals.

Our Astronomical Column.

Comets.—Very careful search for D'Arrest's Comet has been made by photography by Dr. Innes at Johannesburg and Dr. Baade at Bergedorf, Hamburg; several other astronomers have spent much time in visual searching but without success. The comet has not been seen for two revolutions; the perturbations up to 1917 were computed by Mr. Braae, and those for the present revolution by Mr. Cripps, starting with Braae's elements for 1917. As there was a fairly close approach to Jupiter at the last aphelion passage, it is possible that the second-order perturbations, which were not computed, were sufficient to have a considerable effect on the comet's position. If this is not the case, we must conclude that the comet has suffered disintegration, like those of Biela and Brorsen.

Baade's Comet of October 1922 was still under observation in August by Dr. van Biesbroeck at Yerkes Observatory, its magnitude being about 14.

Dr. Strömgren welcomes the observation of comets over long arcs, since it enables the eccentricity of their orbits to be determined. This is of importance in discussing theories of their origin.

The Einstein Shift in the Solar Spectrum.—Two articles on this subject have lately appeared, which both reach an affirmative conclusion on the presence of the shift in the solar spectral lines that Einstein predicted. *Science* for September 28 contains a summary of a paper read by Prof. C. E. St. John to the American Association for the Advancement of Science. It will be remembered that his earlier conclusions tended to the negative side, but this summary makes it clear that he has now reached an opposite conclusion. Details are not given, but the following quotations clearly express his main result. "The lines of the solar spectrum are not identical in position with those due to incandescent samples of the same elements when observed on the earth, and the displacement is toward the red end of the spectrum." "The displacements of the lines . . . predicted by Einstein amount to 86 per cent. of the total observed effect, the remainder being due to other well-known effects."

The other paper is by Dr. J. Evershed in the October issue of the *Observatory*, and gives details of the confirmatory verdict which was announced to the R.A.S. last June. The lines of iron, titanium, calcium, nickel, sodium, cyanogen, were studied in the sun and in the arc; the study covered all parts of the solar disc, the back of the sun being accessible by means of the light reflected by Venus near superior conjunction. The pressure effect is concluded to be negative, the photosphere having a much lower pressure than our atmosphere. He states that "there seems to be very little doubt that the Einstein effect is present in the solar spectrum; the observed shifts . . . seem impossible to explain by motion, pressure, or anomalous dispersion." It remains to find an explanation of the excess of shift shown by the high level lines in the ultra-violet, and the differences given by separate lines.

Research Items.

Disease Godlings in Eastern Bengal.—*Man in India*, a periodical edited by that active anthropologist, Rai Bahadur Sarat Chandra Roy, has steadily improved in value as it has now reached its third volume. Perhaps the most interesting article in an excellent number is that on "The Cult of the Godlings of Disease in Eastern Bengal," by Mr. Sarat Chandra Mitra. He gives further evidence to show that the cults of the higher gods—Brahma, Vishnu, and Siva—retain little influence on the rural populations, which is devoted to the propitiation and control of a mob of malignant demons, who cause disease among men and animals, failure of crops, and other evils which menace the villages.

Tattooing and Lip Distortion.—Two valuable ethnographical articles, both illustrated by drawings and photographs, appear in *L'Anthropologie* (vol. xxxii. Nos. 1-3, August 1923). The first, by Dr. J. Herber, entitled "Les Tatouages du pied au Maroc," describes a remarkable series of foot tattooing in Morocco, the markings taking in some instances an imitation of jewellery, such as anklets, and other decorations of the calf. The second paper, by M. Gaston Muraz and Maddh, Sophie Getsowa, entitled, "Les Lèures des Femmes Djingés, dites Femmes-a-Plateaux," describes the extraordinary types of the labrets used by the Saras-Djingé, improperly called the Saras-Kabas, a tribe of fetish-worshippers in the neighbourhood of Lake Tchad, between the right bank of the Chari and the Arab district of Salamat. The French officers now in charge of this region have taken active measures to prevent this barbaric form of decoration of the female face.

Fatigue Research in Factories.—The Journal of the Royal Statistical Society (July, 1923) contains a paper by Dr. D. R. Wilson on "Some Recent Contributions to the Study of Fatigue." The writer, after giving a short historical outline of the activities of the Industrial Fatigue Research Board, gathers together the conclusions, usually expressed in a tentative way, furnished by several different investigations in different industries. He points out that conclusions, even though they are perforce based on a study of a few individual cases, when confirmed in several widely differing industries, are probably sound. Industrial research as yet is in its infancy, and conditions for carrying it on in a factory bear no resemblance to those of a laboratory. A particular factory may employ only a few individuals on a given process, but, owing to the constitution of the factory, these individuals are typical of any likely to be employed for that process. It therefore seems a likely hypothesis that what is true of these particular individuals with regard to such general problems as the length of the working day, rest pauses, ventilation, etc., will be true of others. It is pointed out that factory research is of the nature of applied science and that the conclusions and methods of several sciences not only have to be utilised, but also adapted, for the particular conditions of factory life.

Mendelian Inheritance in a Fern.—The variations of the hart's-tongue fern, *Scolopendrium vulgare*, are well known and have often been illustrated by Druery and others. Prof. W. H. Lang (*Journ. Genetics*, vol. 13, No. 2) has studied the offspring produced by sowing the spores of a plant which was apparently normal except that one leaf was incised on one side though normal on the other. The prothalli so produced gave rise to young plants 75 per cent. of which were normal (entire leaved) and 25 per cent. incised. The latter, when reproduced by spores, bred true like extracted recessives, while the two entire-leaved offspring both proved to be again heterozygous. The original plant was evidently heterozygous, the normal condition being completely dominant to incised leaf. When spores were sown singly, thus producing isolated prothalli, such prothalli gave rise either to all entire-leaved or to all incised-leaved plants, showing that, in accordance with theory, the segregation of factors had taken place in the spore formation.

Revision of the Catillocrinidæ.—The family of Devonian and Carboniferous crinoids known as Catillocrinidæ is peculiar in combining marked asymmetry in the composition of the cup with but slight asymmetry in its shape; while a large anal tube does not prevent a tendency to symmetry in the fringe of unbranched arms, 11 to 58 in number, which spring directly from the edge of the cup. Mr. Frank Springer's study of this assemblage (Smithson. Misc. Coll., lxxvi. No. 3, Aug. 1923) not only adds new facts to our knowledge of it as well as of the Symbathocrinidæ, but also raises questions of far-reaching importance. These families as well as their allies and admitted ancestors have always been credited with a monocyclic base; in other words no infrabasals have been detected or even supposed to exist in the cup. Mr. Springer now describes and illustrates by photography three small plates hidden within the basals of *Catillocrinus tennesseeae*, the oldest species of the genus. He does not consider that such plates occur in any later members of the family, a fact which may be explained as due to atrophy; but neither does he claim that they may have existed in the predecessors of Catillocrinus. He does, none the less, conclude that these plates are true infrabasals and that "in this species there is a dicyclic base." We hesitate to accept so revolutionary a decision on the evidence of three specimens of one highly modified species. On the other hand, we welcome the support of this distinguished worker for the suggestion that the faunas from Timor which Wanner refers to the Permian are in part of Lower Carboniferous age.

Control of Bunt and Smut.—In Bull. C. No. 3 of the Welsh Plant Breeding Station, K. Sampson describes how satisfactory control of bunt of wheat and covered smut of barley can be obtained by the use of dry copper carbonate, as well as by solutions of copper sulphate and formalin. The dry treatment proved to be good from all points of view save that of cost, but an equally efficacious and less expensive dressing is found in anhydrous copper sulphate and calcium carbonate.

The Gorge of the Arun.—Capt. C. J. Morris on his way back from the last Mount Everest expedition visited the little-known gorge of the Arun in Nepal. He contributes a paper on the subject to the *Geographical Journal* for September. It was known that below the village of Teng the river falls some 4000 feet in 20 miles, and the object of the expedition was to examine this stretch of the river. This drop was found to be due to a steady fall in the bed of the river, which passes through narrow defiles in which the cliffs rise in places to 10,000 feet above the water level. Capt. Morris's paper contains a sketch map of the gorge of the Arun.

Scale for Sea Disturbance and Swell.—On the North Atlantic meteorological chart for October a new scale for sea and swell disturbance is tentatively

suggested. Criticisms or alternative suggestions are invited. The scale, which is proposed by Capt. H. P. Douglas, late Assistant Hydrographer, uses the old notation of 0 to 8 for the sea, and adds 9 for a confused sea caused by currents, tide, a sudden swift of wind, but not necessarily by strong wind. Swell is also shown on a scale of 0 to 9, the main types of swell being designated short, long, low, and high. By a combination of the sea and swell scales, the state of disturbance of the surface waters is expressed by two figures. Thus 43 means a rough sea with a high swell: 37 means a moderate sea with a long heavy swell. The adoption of this or some comparable code and scale would result in greater precision in records than is now possible.

Rainfall in Australia.—Rainfall charts of Australia prepared by the Commonwealth Meteorologist from the records of 1280 well-distributed stations show that in the year 1922 there was an excess above the average rainfall in 21 per cent. of the total area of the continent. In 1923 this figure was 63. During 1922 the totals were the lowest on record in several places between the south-west corner of Queensland and the plains of New South Wales. Throughout the interior from the Lake Eyre basin to the inland parts of Queensland, New South Wales, and Victoria, and also in the north-west of Western Australia, the shortage was considerable, and would have been more pronounced were it not for the heavy falls in December. The areas with rainfall above the average were chiefly in the tropical north, and in the centre and south-east of South Australia. The wheat areas in New South Wales and Victoria experienced a marked shortage, but the falls were so opportune that in most parts a good harvest was secured. It was the pastoral areas of Australia which suffered most severely. The chart gives annual and monthly rainfall maps and a series of insets showing distribution of rainfall above the average in every year since 1908.

Cold Air-waves in the United States.—Prof. R. de C. Ward of Harvard University deals with this subject in the *Scientific Monthly* for May. The author makes reference to cold waves alluded to by past pioneers of weather changes, such as Redfield and Prof. Joseph Henry, who realised the progress of cold periods across the continent, from the Rocky Mountains to Bermuda, prior to the publication of weather maps for the United States. The cold waves were then recognised as associated with the rear segments of cyclonic circulations moving to the eastward. The official definition of a cold wave is a fall of temperature amounting to a certain number of degrees in 24 hours, with a minimum below a fixed standard. Minimum temperatures are not so far below the normal in the north as in the south, and where crops are growing all the year round, frosts are dangerous at any time. For intensity cold waves are practically unique in America, and following as they do warm winds associated with the advance segment of a storm, the sudden drop of temperature is very great, amounting to between 20° F. and 40° F. in the 24 hours. The rapidity of advance is determined by the travelling speed of the cyclonic and anticyclonic areas with which the wave is associated. Three or four severe cold waves are generally experienced each winter in the United States, and they commonly last for two or three days. Various activities and interests are seriously affected during the spell of cold. On the Pacific coast cold waves are few and not severe, and in California the occasional frosts are the product of radiation on clear anticyclonic nights. Northers and blizzards are well described.

Atomic Disintegration.—A paper on the photography of atomic disintegration, by Harkins and Ryan, appears in the Journal of the American Chemical Society for September. Photographs of the disintegration of the atom are given, the retrograde motion of the colliding α-particles being plainly visible. A new type of rays is described, called by the authors ζ-rays; they give very faint but definite tracks. Their range is very many times greater than that of δ-rays, and they are probably due to electrons torn out of the atom, possibly from the K level. In the course of the experiments described, it is remarked that oblique impacts never effect nuclear disintegration.

Sulphur as a Fungicide.—Mr. Harry Curtis Young has recently published (Annals of Missouri Botanical Garden, 9, pp. 403-435, 1922) a valuable contribution to the much-investigated problem as to the reason for the toxicity of sulphur when used as a fungicide for the control of disease upon plants. He finds that sulphur owes its toxic properties to pentathionic acid, an oxidation compound formed from sulphur and water. On this account the sulphur needs to be applied in a very finely divided and therefore easily oxidised form, and he recommends colloidal sulphur liberated in a medium containing buffers so that it is easily maintained at a reaction between P_H 4·0-5·5; above or below this hydrion concentration pentathionic acid is not stable. In the light of this general conclusion there is a brief discussion of the practical problem of producing a suitable sulphur spray or vapour, but the author's investigations on this side of the problem are still in progress.

Petroleum and Natural Gas in America.—The advance chapters on Petroleum (ii. 31) and Natural Gas (ii. 32) of the Mineral Resources of the United States for 1921 appeared recently, and they furnish some interesting data concerning the post-War phase of the oil-industry in that country. Following unsettled conditions for some six months after the armistice, a gradual revival took place culminating in the oil-boom of 1920, but giving place later to a period of intense depression characterised by a serious drop in the price of oil and its various products, the chief economic feature of 1921. In the spring of 1922 a definite improvement was manifest, which has progressed steadily until the present time, when, in fact, the industry is suffering from a vastly different but equally serious malady from that of 1921—overproduction—and for this California is largely to blame. In 1921 there were produced in the United States 472,183,000 barrels of oil and 724,052,000 M cubic feet of natural gas; while the former figure represents a 33 per cent. increase since the end of the War, the latter shows a significant decrease compared with the two previous years, and it is generally conceded that the natural gas industry in America has reached and is gradually passing its peak of production, so that a steady decline may be anticipated for the future. With petroleum the situation is different, and it is difficult to foresee the trend of events, though once California ceases to produce in the present amazing fashion, the decline-curve for the whole country will undoubtedly be apparent. It is interesting to note that the average daily production of oil in the United States at the moment is about 2,400,000 barrels, to which California contributes practically one-third; in 1921, the year under review, the average daily production for the country was approximately 1,300,000 barrels, to which California contributed less than 25 per cent.

Second Triennial Pan-Pacific Science Congress.

MELBOURNE AND SYDNEY, 1923.

THE Science Congress in Australia in August has been, on the whole, highly successful. Between eighty and ninety visitors from overseas joined with a large number of local members in carrying through a fairly extensive programme of work. It is scarcely to be expected that congresses of the kind will receive many, or any, highly important original contributions to science; their value and their opportunity lie rather in bringing together the workers in widely separated countries, enabling them freely to discuss common problems and ideas, but above all to plan broad systematic investigations on the most efficient co-operative bases possible. The principal achievements of this Congress have certainly been in the last-mentioned direction. In nearly every one of the sciences with which it dealt (including agriculture, anthropology, botany, entomology, forestry, geodesy and geophysics, geography and oceanography, geology, hygiene, veterinary science and zoology), there is abundant room for international effort and team work in so vast an area as that within and bordering upon the Pacific Ocean. The recognition of this has been the driving force behind the whole Congress. Many practical proposals have been brought forward, the carrying out of which will do much for the progress of scientific inquiry in this region.

The general organisation, in the hands of the Australian National Research Council, has been much on the lines of a British Association meeting. The scope and value of the whole movement will no doubt rapidly increase. It is already understood that the 1926 gathering will be in Japan (Tokyo and Kyoto), and that the Japanese Government most generously proposes to make available a sum equivalent to 23,000*l*. to cover expenses.

The Sydney session is not yet concluded at the time of writing, but it is possible to give some indication of the main work of the first session, held in Melbourne on August 13-22.

To many, the most important business of the Congress was that faced by the Anthropology and Ethnology Section, which set itself the task of devising a practical scheme for the immediate intensive study of the native races in the Pacific. So far at least as British possessions are concerned, some very definite proposals have been drawn up, in the consideration of which Dr. Haddon, Sir Baldwin Spencer, Mr. W. J. Perry, and, by letter, Sir James Frazer, Prof. G. Elliot Smith, Prof. C. G. Seligman, and Dr. B. Malinowski, have taken part. These have already been received favourably by the Commonwealth Minister for Home and Territories. They provide not only for field workers but also for the establishment of a school in one of the Australian universities for training both scientific workers and Government administrative officers. There is reason to hope for most valuable results in the few years that yet remain before the rapidly disappearing native cultures pass beyond recall. On Sir Baldwin Spencer's initiative, definite schemes for work on the mainland among the remaining wild tribes have also received the support of the whole Congress.

In the Section devoted to Agriculture, it was to be expected that irrigation and land settlement, especially from the economic point of view, would occupy chief attention. Californian and Australian workers, especially, exchanged striking accounts of development work. That the latter could point to an increase in agricultural and pastoral revenue in the Commonwealth from 80,000,000*l*. in 1906 to 260,000,000*l*. in 1921 showed, even after allowing for higher prices and a slightly increased population, how much was being done by agricultural research and education. The chief decision of the section was an insistence upon the paramount importance of soil surveys, showing characters of both soil and subsoil, and, when practicable, the native flora growing on each type of soil. A resolution to this effect will be presented to the Government of every country in the Pacific region.

Botany, Forestry, Entomology, and Zoology Sections conducted many of their meetings in common. Dr. van Leeuwin (Dutch East Indies) gave an account of the progressive changes which have taken place in the vegetation of Krakatoa since the devastation of 1883. The first (wind-borne) arrivals were spore-producing plants. With time the number of new cryptogams decreased. Seeds of flowering plants came, carried either by wind or birds. Casuarinas arrived early and formed forests. These are now being suppressed by later arrivals, which are tropical rain forest plants; the vegetation being at the present time somewhat similar to that existing prior to the volcanic outbreak and exceedingly dense. The study of this vegetation has been a remarkable example of international co-operation, Dutch, British, French, American, Swiss, and German scientific workers all sharing in it.

The much closer connexion in flora between Australia and the Philippines than between the former and the nearer islands to the north-west was due, according to Dr. E. D. Merrill (Manila), to a former land connexion through New Guinea. This land connexion he termed Eastern Malaysia, maintaining that it was separated from Western Malaysia by an area in "unstable equilibrium," bounded on the east by Weber's line and on the west by a modified Wallace's line. This unstable area had to a large extent prevented movements of plants east and west.

The forestry work was chiefly of local interest. Every scientific gathering in Australia points out the supreme folly of the vast destruction of forests which has taken and is still taking place as settlement advances; and this Congress was no exception to the rule.

The entomologists dealt chiefly with problems presented by indigenous and imported insect pests, particularly the various species of termites in Australia and the timber-boring insects of the islands to the north. The dangers threatening Australia were very fully emphasised and will be the subject of communications to Governments.

A discussion on the genetics of domesticated animals initiated by Profs. E. B. Babcock (California), Cossar Ewart (Edinburgh), and W. E. Agar (Melbourne), resulted in a decision by the Zoology Section to form a special committee of five geneticists to collect information on all genetic research now in progress in Pacific countries and to report to the next Congress. The protection of native fauna was strongly emphasised here, too, every country insisting on the international importance of preserving from destruction much of the unique fauna of Australia. A public meeting was held during the Congress to give support to local authorities in contemplated action towards this end.

With Sir Gerald Lenox-Conyngham and Dr. E. F. J. Love in charge of the Section of Physics, it was natural that geodesy should be very much to the fore. The slight contributions made so far by Australia to this science were contrasted with the

great significance of the study from economic and national defence points of view, and with the chance which Australia has, from its geographic position, form, and dimensions, of making a highly important contribution to knowledge of the figure of the earth and of the form of the lithosphere.

The wide work on terrestrial magnetism being carried out chiefly by the United States was discussed at some length, and again Australia was urged to take up her fair share of it. The desirability of continuing and extending the work of the non-magnetic ship *Carnegie* was affirmed. Other highly interesting subjects cannot be more than mentioned by name, such as gravity work in Japan and the Philippines; earth tides and their employment for determining earth rigidity; pulsatory vibrations and the causes of destruction by earthquakes, with an account of safeguards to property adopted in Japan; international solar physics research; determination of gravity at sea; comparison of accuracy of wired and wireless longitude determinations.

Three matters stand out in the work of the Geography and Oceanography Section. The first is the presence in Sydney Harbour of the new U.S.A. scout cruiser *Milwaukee* (10,000 tons; 35 knots), specially sent out by the American Government to demonstrate to the Congress the Sonic Depth Finder. The vessel has journeyed some ten thousand miles and has obtained a chart of the Pacific bed over which it passed. While the instrument is not yet fully perfected, its value not merely for rapidly obtaining accurate knowledge of the sea bottom, but also in increasing the safety of vessels in many of the intricate channels among the Pacific islands, very greatly impressed the Congress, while the object-lesson of a fighting vessel devoted to scientific work was a valuable one. The second was a full exchange between the countries represented of information as to what they are doing (or, in the case of Australia, merely beginning to do) in the matter of hydrographical surveys. A very fine exhibition of maps was made, principally from the Royal Topographical Service of the Dutch East Indies. Prominence was given to the need for work in the neighbourhood of the Great Barrier Reef and elsewhere. In some regions, charts drawn by Matthew Flinders are still perforce being used. The third subject of importance was the pressing need for co-ordination of meteorological work in the Pacific. There are now numerous stations, working independently, overlapping, and apparently incapable of co-ordination among themselves. The solution urged was the appointment of a British officer at Samoa, it being believed that in no other way could the difficulties in the way of the needed association of activities be established.

Geology possessed numerically the largest Section of all, and a huge amount of matter, nearly all descriptive, was put before it. Indeed, a "pool" of geological information was created, every country contributing as much to it as time, very strictly allotted, would permit. It is impossible to set out briefly the nature of the work discussed; the main subjects have already been indicated in a former article. Between section meetings the geologists distributed themselves over the countryside.

The Hygiene Section went fully into problems connected with mining industries, under the leadership of Drs. R. R. Sayers (U.S.A.), Watkins Pitchford (South Africa), and J. H. L. Cumpston (Australia). Methods of ventilation, sanitation, and medical examination were discussed from different points of view. The progress of the hookworm campaign was followed. In Queensland, where 12 per cent. of the miners are affected, the value of this work is being fully demonstrated.

The establishment of an international organisation, with a number of mobile units moving from island to island introducing methods of modern preventive medical science, is deemed essential if the present dwindling of population of native races in many island groups is to be arrested. New Caledonia in 1853 had 70,000 natives; in 1900 the number was 19,000. Measles from Sydney killed 26 per cent. of Fiji's population in 1875, while influenza in 1918 took off 20 per cent. of the natives of Samoa. There is also continuous heavy toll taken by tuberculosis and venereal disease. A basis for part of the discussion was provided by results, obtained from a widely circulated *questionnaire*, showing the distribution of such diseases as plague, smallpox, leprosy, malaria, beri-beri, and others.

In view of the importance of animal life in the economic positions of most of the Pacific countries, a joint discussion between the Hygiene and Veterinary Science Sections on the difficult subject of international animal quarantine regulation had more than passing interest. The fact that "surra" in the Philippines makes it impossible for horses to be kept shows the significance of the whole matter to Australia. Definite proposals have not yet been submitted to the full Congress.

It will be seen that throughout, the main functions assumed by the Congress have been to examine carefully existing lines of work, and then to point to outstanding needs for individual and combined effort in tackling the innumerable scientific problems of the Pacific region. The extent to which such stimulus will lead to action during the next three years will be the test of the value of a meeting of the kind.

A. C. D. R.

Diseases of Fruit in Storage.

ATTENTION was recently directed in Nature (vol. 111, April 14, p. 516) to the direct efforts now being made in the United States to open up a new field of service for plant pathology, through the study of the best conditions for preserving fruit and vegetable produce in the market and in transit.

It would seem that in Great Britain, in a less direct manner, through the activities of the Food Investigation Board, working under the auspices of the Department of Scientific and Industrial Research, the same field of service is gradually opening to the scientific investigator. Thus the work of Mr. F. T. Brooks and his collaborators upon the fungus organisms contaminating chilled meat, recently noticed in Nature (vol. 111, April 28, p. 582), was carried out for this Board, which has now issued, as Special Report No. 12, a report upon "brown heart"—a functional disease of apples and pears, by Dr. Franklin Kidd and Dr. Cyril West.

Occasionally when apples and pears are in storage, or when in transit by ship to Great Britain, although entirely healthy to outward appearance, the inner portion of the fruit decays and turns brown; no organism is found to be present as the cause of this diseased condition, which may be widespread.

The authors report that, in 1922, this internal decay, which they have described as "brown heart," was so prevalent among apples imported from Australasia as to arouse anxiety among those connected with the fruit trade. In a report which is singularly direct in

its analysis of the cause of the practical problem and in indicating the direction in which prevention of the disease may be looked for, the authors show clearly how laboratory investigations, at first sight remote from the practical problem, contribute to its solution.

Laboratory experiments have shown that an exactly similar "brown heart" condition may be produced in home-grown apples, under carefully controlled conditions which leave no doubt that the internal decay takes place when the concentration of carbon dioxide in the internal atmosphere, in the air spaces ventilating the tissues of the apples, exceeds a certain toxic limit. The ventilating system and its communication with the external atmosphere, varies with the variety of apple; naturally, therefore, the toxic limit is reached with different rapidity in different varieties, and thus a reasonable explanation is found of the different varietal susceptibility to "brown heart."

The authors establish experimentally that within wide limits the oxygen concentration is not responsible for "brown heart," and their examination of the ships' holds where "brown heart" has appeared during the voyage confirms the view that it is to be associated with a high percentage of carbon dioxide in the hold where the apples were stored. Thus the importer, the grower, or salesman concerned with the storage of apples and pears has his attention directed to one clearly defined pathological condition to which the fruit is subject, and at the same time a clear suggestion as to the direction in which a remedy may be found.

Incidentally the authors think that their work also elucidates an old-standing problem of the grower, whose apples frequently suffer from a functional disorder known as "bitter-pit." Brown discoloured patches appear just under the skin of the apple and dry up leaving the pits. The original browning and decay seems to be exactly similar to the internal decayed tissue in "brown heart," and is probably traceable to the same cause, a local excess of carbon dioxide in the tissue just below the skin which then turns brown. This suggestion will greatly interest apple growers. "Bitter pit" much depreciates the value of a good apple, and attention will certainly be turned to the possible causes of such local excessive accumulations of carbon dioxide in the ventilating system of the apple tissue.

The New Mechanics.[1]

It is interesting to speculate on the forecasts which would have been made at the beginning of the century as to the condition of physical theory now. The state of knowledge at that time would have suggested that the atomic theory would proceed to develop along the lines of the older mechanics. One or two phenomena already known did not seem to fit in very well, but it was not very unreasonable to suppose that the increase of knowledge would remove these difficulties. The physicist of that time would not have conjectured what has actually come to pass. There are at present two great bodies of doctrine, either of which seems to hold over a wide field, but neither of which can be at all reconciled with the other. Nature is more like both than like any compromise between them. Of these two doctrines, one is the old-fashioned mechanics, which works for many atomic phenomena; the other—the new mechanics—is known as the *quantum theory*. The underlying true mechanics are really quite unknown, but we have a curious set of rules which have an extraordinary knack of giving the right answer; the branch of mathematics with which these rules are most closely connected is, rather unexpectedly (and with a good deal of qualification), elementary arithmetic. It is the purpose of the lecture to illustrate this.

The first illustration is "atomic number." It has been found possible to number off all the elements known to chemistry, starting from hydrogen 1, helium 2, and so on up to uranium 92, and these numbers have a simple physical meaning which is the most important thing that can be said about the elements. The atomic number is simply the total number of *electrons* which revolve round the *nucleus* of the atom. It can be studied in a variety of ways, of which the most striking is the α-ray photographs of C. T. R. Wilson.

More complicated illustrations are given by the Bohr theory of spectra. The best approach to the subject is through the phenomenon of resonance potentials. If an electron strikes an atom with more than a certain amount of energy, the collision is inelastic and the energy is radiated away all in one wave-length. The collision has raised the atom from one definite condition to another, and the return causes the emission. A complete theory of the hydrogen spectrum has been founded on this idea, and as a result of this theory the various conditions of the atom can be described by labelling the electron (there is only one in hydrogen) with two numbers—thus 4_2 or 6_1. In the higher elements the same idea works and each electron has certain numbers associated with it; here, however, the number pairs have not quite the precisely defined dynamical meanings that can be given them in hydrogen. The spectral lines can also be described in terms of numbers. These numbers have not yet been made to yield the absolute values of the wave-lengths, but it is possible by their means to unravel the general characters of what are often highly complicated systems of lines. For a line, two groups of numbers are required, such as $5(3,2) \rightarrow 2(2,2)$, and there are rules as to what pairs of numbers may go together—for example, the second members of the two groups can differ only by 1, the third by either 1 or 0, whereas the first may differ by any amount. There is still a great deal of work to be done on the subject, but it seems probable that all spectra will at no very distant date be brought under rules of this kind.

This is a very incomplete sketch of the successes of the quantum theory, but that theory is only a partial view of the whole of Nature, because it leaves out of account certain indirect ways in which spectral lines exhibit themselves. The chief of these are the ordinary processes of reflection and refraction of light, which are very well explained on the older theory. A reconciliation of the two views seems at present quite impossible, and this can only mean that there are fallacies in some of the fundamental assumptions that we make unconsciously. Of these almost the only ones, that it would do any good to abandon, are the belief in the continuous nature of time and space, beliefs which have been disturbed by the Relativity Theory of Einstein, which will probably have to be once again revolutionised to reconcile atomic theories. To any one who finds difficulty in Einstein's theory, and that is to every one, this is a rather depressing prospect, but it is quite possible that the new revolution, whatever it may be, will tidy up the whole field and make it easier to deal with, even though it will superficially be less like than before to our crude ideas of the nature of the world.

[1] Synopsis of an address delivered on October 16 at the University of Edinburgh by Prof. C. G. Darwin, the first occupant of the Tait chair of natural philosophy in the University.

University and Educational Intelligence.

Cambridge.—Mr. F. J. W. Roughton and Mr. W. R. Dean have been elected to fellowships at Trinity College.

A letter from the Chairman of the University of Cambridge Commissioners has been received inviting representations from University bodies and from individual members or groups of members of the Senate on matters in which they desire the proposals of the recent Royal Commission to be modified. These should be sent before the end of the year to the Secretary to the Commissioners, Mr. H. A. Hollond, Trinity College.

Edinburgh.—Prof. J. J. R. MacLeod, professor of physiology in the University of Toronto, who was awarded the Cameron prize for 1923, delivered two lectures in the University on October 16 and 17 respectively, on the nature of control of the metabolism of carbohydrates in the animal body. He dealt with the discovery of insulin and its value in the investigation, not only of diabetes, but also of other problems of metabolism. The Cameron prize was founded in 1878, and is awarded to an investigator who in the course of the five years immediately preceding has made an important addition to practical therapeutics.

Prof. T. J. Mackie, formerly professor of bacteriology in the University of Cape Town, who was recently appointed Robert Irvine professor of bacteriology, devoted his inaugural address to a survey of the present position of medical bacteriology. Prof. Mackie has made arrangements for developing the teaching of bacteriology as a subject for the degree of B.Sc.

Dr. J. E. M'Cartney has resumed duty as lecturer in bacteriology after a year's leave of absence granted to enable him to carry out researches on certain filterable viruses in the Rockefeller Institute.

Leeds.—The West Riding County Council has decided to devote the proceeds of a penny rate to the assistance of university education, which has already in the past been consistently supported by the Council.

Mr. W. F. Shanks has been appointed professor of physiology. Dr. Shanks graduated B.Sc. at the University of Glasgow in 1913, with special distinction in physiology, and M.B., Ch.B., in 1915 with commendation. In 1920 he was appointed lecturer in physiology at Glasgow and acted as senior assistant to the Regius professor of physiology. For the last three years he has also been in sole charge of a special course in physiology for the new degree of Bachelor of Education (Glasgow), in which the subject is treated from a special point of view with regard to the physiology of the child, psychology, and other cognate aspects.

The following further appointments have been made: Mr. F. J. Brown to be assistant lecturer in zoology; Mr. A. W. Anderson and Mr. J. McGregor, district lecturers in agriculture; Mr. G. Milne, temporary assistant lecturer in agricultural chemistry; Mr. H. Preston, assistant science tutor; Miss M. K. Morgan, assistant lecturer in geography; and Miss E. Newcomb, assistant lecturer in education.

London.—Free public lectures on "The Treatment of Injuries of the Long Bones produced by Accident or Disease" will be delivered by Prof. E. W. Hey Groves at Guy's Hospital Medical School at 5.30 on November 8, 9, 12, and 13.

Societies and Academies.

London.

Optical Society, October 11.—E. T. **Hanson**: Notes on the elementary algebraic theory of a class of photographic objectives. Equations expressing the absence of Seidel's first four aberrations in an objective consisting of two thin systems of lenses, separated by an interval, are formed. When each of the two thin systems consists of only two lenses, the equations can be put in a form which admits of an elegant graphical solution, regard being paid to the necessity of obtaining a solution in which no one of the lens curvatures exceeds a certain limit.—T. **Smith**: A general survey of the thin double lens. The shapes of the lenses and the types of glass suitable for the construction of an objective free from all first-order aberrations in a primary plane for an infinitely distant object are found on the assumption that the system is composed of two separated thin lenses, each of which consists of glasses cemented together. The analysis indicates that "old" achromats should be used for both component lenses, a conclusion not in accordance with modern practice.—T. F. **Connolly**: New types of levelling instruments using reversible bubbles. A true level can be obtained using reversible bubbles, as the mean of two observations from a single station. The theory is then applied to the design of various types of "self-adjusting" levels and to the adjustment of a collimator.

Paris.

Academy of Sciences, October 1.—M. Albin Haller in the chair.—A. **Lacroix**: The composition of the meteorite which fell at Saint-Sauveur (Haute-Garonne) in 1914. The examination by metallographic methods proved the presence of metal (nickeliferous iron) and enstatite, with smaller proportions of clino-enstatite, oldhamite, maskelynite, apatite, and graphite. A complete chemical analysis is given, the portion removable by acids (mainly metallic) being examined separately.—Emile **Picard**: H. G. Zeuthen.—Vito **Volterra**: The movement of a fluid in contact with another fluid and surfaces of discontinuity.—Maurice **Gevrey**: The formation and use of Green's functions in the integration of linear partial differential equations of any order whatever with imaginary characteristics.—F. H. **van den Dungen**: New technical applications of integral equations.—Antoine **Zygmund**: On trigonometrical series.—R. **Jacques**: Two networks the two tangents of which belong to linear complexes and the transformations of the equations of the surfaces of constant total curvature.—Serge **Bernstein**: The principle of stationarity and generalisations of Mendel's law.—P. **Stroobant** and P. **Bourgeois**: Certain stars the movements of which are parallel and equal to that of the sun.—Paul **Pascal**: The slow formation of a definite compound in mixed crystals. Some anomalies in the cooling curves of mixtures of benzylidene-aniline and anisylidene-aniline have been shown to be due to the slow formation of a definite compound of one molecule of the latter compound with two of the former.—René **Dubrisay** and Pierre **Picard**: The capillary phenomena manifested at the surface of separation of water and vaseline oil in the presence of fatty acids and of alkalies. The drop volume method has been applied to the study of the changes in the surface tension at the surface of separation of vaseline oil and aqueous solutions. The latter included solutions of caustic soda and sodium carbonate, of sodium carbonate and sodium bicarbonate, and of caustic soda with common salt.—H. **Gault**: The soluble ester salts of starch and

the higher fatty acids. Ordinary starch, suspended in a mixture of pyridine and toluene, heated with lauryl chloride, gives a dilaurate of starch. Details of its properties and analysis are given.—Adrien **Guébhard**: The Japanese earthquake.—E. **Rothé**: Earthquakes in France in 1920–21. A table giving locality, time, degree, and epicentral region of nine earthquakes in 1920 and six in 1921. The greatest seismic activity was in the region of the Pyrenees.—E. G. **Mariolopoulos**: The formation of local Mediterranean depressions and the Norwegian theory of the "polar front." The local Mediterranean depressions appear to be formed in accordance with the Norwegian theory of the "polar front."—A. **Guilliermond** and G. **Mangenot**: Cytological observations on the mode of formation of essential oils. The method adopted is based on the selective staining power of indophenol blue. The sections are made by hand or in the freezing microtome, stained, and observed in water. The results of the observations do not confirm the view that there is a relation between tannoids and essential oils.—M. **Prianichnikov**: The assimilation of ammonia by the higher plants. The experiments cited lead to the conclusion that the plant, whether green or etiolated, absorbs ammonia energetically from ammonium salts. Nitrates must be reduced to ammonia before absorption by the root. If in agriculture, the development of the plant is roughly proportional to the rate of nitrification, the causes are of a secondary nature; anything which prevents nitrification, such as acid reaction or insufficient aeration, also prevents the development of the higher plants, so that the nitrification is an important criterion of the condition of the soil.—V. **Lubimenko**: The specific action of light rays of various colours in photosynthesis.

WASHINGTON, D.C.

National Academy of Sciences (Proc. Vol. 9, No. 9, September).—J. **Stieglitz**: (1) A theory of colour production. By reduction, every dye becomes colourless, forming the "leuco-dye"; by oxidation of the latter, the colour is restored. Indophenol owes its colour to the combination within the molecule of a strong positive oxidising atom with a strong negative reducing atom. Colour intensity is increased by increasing the reducing side with a base. The reducing electrons are freed sufficiently from *intra*-atomic restraints to permit vibrations which absorb a portion of white light, the complementary colours appearing in the dye. A similar argument is used to explain the colour of basic dyes such as pararosaniline. (2) A theory of colour production: inorganic compounds. Colour may be produced by a loosely held electron in an atom with an odd number of valence electrons (G. N. Lewis), by *intra*-atomic or *inter*-atomic oxidation reduction potentials, or by both the latter, in the manner similar to that described above in (1).—G. **Strömberg**: The asymmetry in the distribution of stellar velocities (see NATURE, October 20, p. 600).—W. J. **Luyten**: On the mean absolute magnitudes of the K and M giants and the systematic errors in trigonometric parallaxes. The mean absolute magnitude of the Ko giants, assumed to be independent of their position in space, is about $+0\cdot7$ mag.; that of the M giants is about $-0\cdot2$ mag. No large systematic error is found in the Allegheny trigonometric parallaxes.—C. E. **Seashore**: Measurements on the expression of emotion in music. Musical expression can be conveyed entirely by the sound wave: frequency determines pitch, amplitude intensity, duration of the single wave extensity, and the form of the wave timbre. All these factors can now be recorded and analysed; *e.g.*, the vibrato in singing is a synchronous pitch and intensity pulsation of about 6 oscillations a second.—G. A. **Miller**: Groups of order 2^m in which the number of the sub-group of at least one order is of the form $1+4k$.—L. **Thompson**: The motion of a falling chronograph projectile. With this instrument, neither the projectile being timed nor the projectile of the chronograph which carries the photographic surface for taking the record, strikes a material object during the experiment. Corrections are made for the influence on the early motion of the chronograph projectile of the magnet from which it is released and also for air resistance. The instrument measures with an error not greater than 1/2,000,000th sec.

CAPE TOWN.

Royal Society of South Africa, August 15.—Dr. A. Ogg, president, in the chair.—M. **Rindl**: Preliminary note on the active principles of the yellow tulip (*Homeria pallida*). The alcohol extract, after removal of the solvent, was separated into a water soluble portion and into a resin. The former yielded crude alkaloid equivalent to 0·017 per cent. calculated on the weight of the plant material. Only 23 per cent. of this is water soluble, and the stems and leaves seem to owe their toxic properties mainly, if not entirely, to this water soluble alkaloid. The alkaloid exerts a digitalis-like action on the circulation, and in large doses is a cardiac poison. Its action is not cumulative. The aqueous solution appears to contain two other alkaloids differing in their behaviour towards organic solvents, as well as an organic base. A primary amine and a very small amount of a glucoside were detected. Extracts from the corms and sheaths contain active substances of the nature of a cardiac tonic. They are very poisonous, and administered to animals in successive small doses, they send the heart into fibrillation and cause sudden death.

SYDNEY.

Royal Society of New South Wales, September 5.—Mr. R. H. Cambage, president, in the chair.—E. H. **Booth**: Atmospheric dust and atmospheric ionisation. A persistent nucleus—which is presumed to be the Langevin large "ion"—requires for condensation a supersaturation 1·075, corresponding to a diameter of $1\cdot25\times10^{-6}$ cm., taking the density as unity. This is not found in filtered air, nor does it grow in filtered air. It may be produced in filtered air if the air is bubbled through water, although the condensation can be in no way dependent on electrification effects. A "foreign" nucleus is essential; electrification merely enables it to be recognised by mobility tests.—A. R. **Penfold** and R. **Grant**: The germicidal values of Australian essential oils (exclusive of Eucalypts) and their pure constituents, together with those for some essential oil isolates and synthetics. Pt. 1. When tested against *B. typhosus*, the pure constituents, as well as a number of isolates and synthetics, were found to possess coefficients varying from 6 to 20, ketones, alcohols, and a number of phenols possessing well-marked germicidal properties; 1 per cent. suspensions of the bodies examined were prepared in 7½ per cent. rosin soap solution for examination. The phenol ethers, safrol, and isosafrol were found to possess coefficients of 11 to 12. Thymol manufactured in Sydney from piperitone gave the same coefficient as the natural isolate, 25.—A. R. **Penfold** and F. R. **Morrison**: Preliminary note on the electrolytic reduction of piperitone. The preparation in quantitative yield of isomenthone from piperitone by electrolytic reduction at 20-30° C., using a nickel cathode. A current density of 3·5 to 4 amp. was employed with an E.M.F. of 6-10 volts,

the reaction being completed in 12-13 hours using 100 c.c. of ketone. Highly lævo-rotatory samples of piperitone yielded menthone of high dextro-rotation, the semicarbazone of which melted at 113° C.

Official Publications Received.

Commercial Intelligence Department, India. Agricultural Statistics of India, 1920-21. Vol. 2: Area, Classification of Area, Area under Irrigation, Area under Crops, Live-Stock, and Land Revenue Assessment in certain Indian States. Pp. v+205. (Calcutta: Government Printing Office.) 1.8 rupees.

Reprint and Circular Series of the National Research Council. No. 46: Problems in the Field of Animal Nutrition. By Sub-Committee on Animal Nutrition. Pp. 9. (Washington: National Academy of Sciences.) 15 cents.

Bergens Museums Aarbok, 1921-1922. 1 Heft. Pp. 28+26+41+23+5+50. (Bergen: A/S John Griegs Boktrykkeri og N. Nilssen & Søn.)

Department of Agriculture, Tanganyika Territory. Report for the Year 1922. Pp. 30. (Dar-es-Salaam.)

Arbeten utgifna med Understöd af Vilhelm Ekmans Universitetetsfond, Uppsala. 29: Die Goten und Langobarden in Italien. Von Nils Åberg. Pp. viii+166. (Uppsala: Almquist & Wiksells Boktryckeri A.-B; Haag: M. Nijhoff; Leipzig: O. Harrassowitz; Paris: Honoré Champion.)

U.S. Department of Agriculture. Farmers' Bulletin No. 1321: Fumigation of Citrus Trees for Control of Insect Pests. By R. S. Woglum. Pp. 59. (Washington: Government Printing Office.) 10 cents.

Diary of Societies.

MONDAY, OCTOBER 29.

INSTITUTE OF ACTUARIES, at 5.—W. Palin Elderton and H. J. P. Oakley: Notes on the Interpretation of "Select" Rates of Mortality.

ROYAL COLLEGE OF SURGEONS OF ENGLAND, at 5.—Prof. Shattock: Actinomycosis: Madura Disease.

TUESDAY, OCTOBER 30.

INSTITUTE OF MARINE ENGINEERS, INC., at 6.30.—Viscount Curzon: Presidential Address.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Dr. C. E. K. Mees: Amateur Kinematography.

ROYAL SOCIETY OF MEDICINE, at 9.—Presentation of Gold Medal to Prof. Gowland Hopkins, who will lecture on Stimulants of Growth.

WEDNESDAY, OCTOBER 31.

SOCIOLOGICAL SOCIETY (at Royal Society), at 8.15.—Sir W. M. Flinders Petrie: The Growth and Decay of Communities (Lecture).

THURSDAY, NOVEMBER 1.

ROYAL SOCIETY, at 4.30.—E. G. T. Liddell and Sir Charles Sherrington: A Comparison between certain Features of the Spinal Flexor Reflex and of the Decerebrate Extensor Reflex respectively.—J. Barcroft and H. Barcroft: The Blood Pigment of Arenicola.—T. Deighton: The Basal Metabolism of a Growing Pig.

ROYAL AERONAUTICAL SOCIETY (at Royal Society of Arts), at [illegible].—Major Wimperis: Some Recent Developments in Aircraft Instruments.

INSTITUTION OF ELECTRICAL ENGINEERS, at 6.—W. Wilson: Industrial Research, with special reference to Electrical Engineering Development.

CHEMICAL SOCIETY, at 8.

FRIDAY, NOVEMBER 2.

INSTITUTION OF MECHANICAL ENGINEERS, at 6.—Sir Westcott S. Abell: The Mechanical Problems of the Safety of Life at Sea. (Thomas Hawksley Lecture.)

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—S. J. Taylor: Photographic Perspective.

JUNIOR INSTITUTION OF ENGINEERS, at 7.30.—D. V. Hotchkiss: Hydraulic Propulsion.

PHILOLOGICAL SOCIETY (at University College), at 8.—Prof. F. Newton Scott: American Idiom.

ROYAL SOCIETY OF MEDICINE (Anæsthetics Section), at 8.30.—Dr. H. Featherstone: A Critical Report on 100 cases of Spinal Analgesia with Tropacocaine.

SATURDAY, NOVEMBER 3.

ROYAL SOCIETY OF MEDICINE (Otology Section), at 10 A.M.

GILBERT WHITE FELLOWSHIP (at 6 Queen Square, W.C.1), at 3.—Dame Helen Gwynne-Vaughan: The Mechanism of Inheritance.

PUBLIC LECTURES.

SATURDAY, OCTOBER 27.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—E. Lovett: The Legendary Folklore of the Sea.

MONDAY, OCTOBER 29.

UNIVERSITY COLLEGE, at 5.—Miss Iza Thompson: The Teaching of Speech to Deaf Children.

MEDICAL SOCIETY OF LONDON, at 5.15. Dr. C. K. Millard: The Disposal of the Dead. (Chadwick Lecture.)

WEDNESDAY, OCTOBER 31.

ROYAL INSTITUTE OF PUBLIC HEALTH, at 4.—Major H. G. Anderson: Air Accidents and the Hygiene of Aviation.

UNIVERSITY COLLEGE, at 6.15.—H. Higgs: The Part of Statistics in Civic Education (Newmarch Lectures). (Succeeding Lectures on November 7, 14, 21, 28, and December 5.)

THURSDAY, NOVEMBER 1.

ROYAL SOCIETY OF MEDICINE, at 5.—Dr. A. Logan Turner: The Advancement of Laryngology: A Plea for Adequate Training and Closer Co-operative Action. (Semon Lecture.)

KING'S COLLEGE, at 5.30.—R. Aitken: The Geography of Spain and Typical Spanish Institutions. (Succeeding Lectures on November 8, 15, 22, and 29.)

FRIDAY, NOVEMBER 2.

UNIVERSITY COLLEGE, at 5.—Prof. G. Dawes Hicks: The Fundamental Concepts of Natural Science. (Succeeding Lectures on November 9, 16, 23, 30, and December 7.)

SATURDAY, NOVEMBER 3.

HORNIMAN MUSEUM (Forest Hill), at 3.30.—Dr. C. A. Raisin: Volcanoes.

Aeronautical Research.

"PROGRESS in aeronautical research has, throughout the year, been continuous but slow." This, the opening sentence of the report of the Advisory Committee for Aeronautics for the past year, indicates a measure of anxiety and leaves the impression that, in the view of the Committee, insufficient attention is being paid to the researches which it advises.

A further paragraph makes a note of the view that "Funds devoted to research by trained staffs will give a better return to the State than the offer of large sums as prize money for limited lines of attack on the problems of flight." The reference here is obviously to the prize offer of 50,000*l.* for a successful helicopter, and it would appear that the Aeronautical Committee dissociates itself from that scheme. In all these matters, however, and under the most favourable conditions, the Committee can only tender advice; all executive action rests with the Air Ministry.

In spite of a machine which, when dealing with scientific matters, grinds at every turn of the wheels, progress is reported in many directions. A wide range of subjects for research is dealt with but the degrees of urgency are very variable. There are problems connected with the trustworthiness of aero engines and their economical running. Fire prevention in aircraft is studied by a special sub-committee, and recommendations have been made which may be expected to reduce substantially this type of flying risk. The properties of metals, particularly in regard to fatigue, are receiving much attention in view of the fact that aeronautics depends for success on the building of light structures with a definite minimum of strength, and that the ordinary uses of metals in engineering practice do not call for a degree of refinement essential to aircraft construction. None of these problems, however, possesses the present importance and urgency of a closer examination of the aerodynamic properties of aeroplanes than has hitherto been attempted. Flight under critical conditions is required with the necessary instruments for accurate observation by a trained staff. The bottle neck of research occurs precisely at this point; for there is no specific allocation of staff for scientific research.

We have all had recent opportunities of observing the results of public inquiries into one or two cases of fatal accident arising during the use of civil aeroplanes. It may have been noticed that no blame is attached to individuals, and that the causes of the accidents are returned as unknown. In a certain sense no objection can be taken to such findings; indeed, they can be heartily endorsed so far as personnel is concerned. On

the other hand, it is believed that, so long as aeroplane design is based on unextended knowledge, so long will the consequences of human error in the piloting of an aeroplane be severe.

The preliminary cause of accident may be any one of a hundred and one things; in the great majority of cases the final steps leading to a crash are the same. An aeroplane cannot maintain itself in steady flight at a speed below a certain critical value called the "stalling speed," a value which in the commercial craft of the day is rarely less than 50 m.p.h. The direct consequence of this is unimportant, but the secondary effect is vital since at 45 m.p.h. such an aeroplane is uncontrollable. Usually the aeroplane first rolls violently, then puts its nose down and dives almost vertically into the ground at a speed of 70 to 80 m.p.h. The shock-absorbing mechanism fitted in the undercarriage never comes into operation.

Every pilot knows the sequence of events and tries to avoid stalling at the same time as he is anxious to reduce his speed when approaching unfavourable ground in a forced landing: in spite of skill, the inevitable error happens on an appreciable number of occasions. The rules for recovery from stalling are also perfectly well known, but in order to apply them the pilot requires a free fall of not less than 500 ft. If he is only 200 ft. from the ground the stalling of an aeroplane must lead to a crash. Must it always be so? The Aeronautical Research Committee does not think so, as may be seen from the following quotation:

"The results already achieved at the Royal Aircraft Establishment . . . are distinctly encouraging, particularly as regards the full scale experiments on stalled flight, and the Committee wish to pay a tribute to the skill shown by the pilots in their pioneer work.

"The present position is, however, that although maintained stalled flight is definitely possible, neither the stability nor the control of the aeroplane are such that flight near the ground may yet be regarded as safe, and since there do not appear to be any insuperable difficulties in the way, there is a very strong case for pushing forward. . . ."

Reading more fully in the report shows that the Committee believes in the possibility of ultimately designing aeroplanes which can be kept on an even keel in an emergency, and so touch the ground with apparatus specially introduced for taking the shocks of landing.

The Air Ministry has responded to the advice of the Committee to the extent of ordering two special machines for the necessary research. This is, we believe, the first time in the history of British aeronautical research that experimental conditions have had precedence in determining the design of an aeroplane, and the announcement of the fact by Sir Geoffrey Salmond at the Air Conference at the beginning of the year was generally welcomed and appreciated by all branches of scientific and technical activity in aeronautics. It will be some time before the aeroplanes are ready for use, and it is probably in relation to the conditions under which they will be used that the Aeronautical Research Committee has reason for anxiety. The present association of scientific research with routine experiment has been unfortunate, and the initiative in aeroplane design has—like the Schneider Cup—gone from Britain to America. All the important flight records, for speed, height and endurance, are held by the United States of America, together with the palm for energy devoted to research.

The situation does not appear to be one which will automatically right itself, and the belief is growing that the remedy will only come by placing a scientific man on the Air Council. British business instincts, if one may judge from such an example as that of the British Dyestuffs Corporation, still shy at the idea that scientific knowledge is required in the supreme administration, but events will probably determine the issue against them. In the meantime, one can only hope that the Aeronautical Research Committee will on later occasions be able to report that "progress is continuous" even if "slow." L. BAIRSTOW.

Biology at the Cross-roads.

Emergent Evolution: the Gifford Lectures delivered in the University of St. Andrews in the Year 1922. By Prof. C. Lloyd Morgan. Pp. xii+313. (London: Williams and Norgate, 1923.) 15*s*. net.

PROF. LLOYD MORGAN'S Gifford Lectures delivered at St. Andrews last year and now published are a constructive essay in evolutionary naturalism which, he warns us, Huxley would not accept, and that upon more counts than one. It is true that acceptance by Huxley, or by any one else, is inadmissible as a standard of reference for the verification of fact or theory in science; but the question at once arises: if the biological standards of an earlier generation are not those of to-day, wherein and why are they not? The occasion is not provided by Prof. Lloyd Morgan alone: in a multiplicity of forms the question echoes and re-echoes unanswered in the hearing of biologists who appear strangely inattentive alike to its insistence and its import. In the literature of systematic research, little enough of this appears; but in all kinds of periodicals less intensive and austere, and from all manner of platforms approachable by a public, ill-informed possibly, but

certainly inquisitive, the implied incertitude of biology provides unending material for thought.

It seems, indeed, that the technical literature has ceased to reflect the form and content of modern biological inquiry, for what else is the significance of the fact—if fact it is—that those who contribute preponderatingly to its mass and volume, workers and teachers in the universities, are, in their academic privacy, increasingly dubious concerning the fundamentals of their science? Tribute is still paid to the Darwinian theory, some of it good coin, most of it lip-service unwholesomely rich in ambiguity. Behind the Darwinian theory are its implications, very far-reaching, inescapable, but for the most part disregarded and feared. Still behind, entering into and doing more than a little to guide the course of discussion, a shady and scarcely mentionable background, is the fear of a democracy crudely godless. The kind of verbatim reporting and rapid snapshotting of Nature which to-day passes as biological research can lead at best to a mere reduplication of the universe: to a vast library edition of the facts of Nature, less rather than more orderly than the original, and less profitable to consult with advantage. But that does not mean that the mode of attainment or the constitution of scientific knowledge has changed since the middle of the nineteenth century, or that science owes any obligation to social exigency or individual composure. The present state of biology is not healthy.

We have brought these considerations to the reader's mind because they constitute the essential circumstances for the discussion of Prof. Lloyd Morgan's book. It is on their account that the two aims of the work must be distinguished. One is an examination of the ideas constituting the modern theory of relations to discover whether they may not yield something of value for biology: the other is a personal affair of the author and of such of his readers who, with him, hold the "proper attitude" of naturalism to be "strictly agnostic" and yet "cannot rest content" with it. It has always seemed to us that satisfaction with Prof. Alexander's view of deity is more intelligible in those who do not fully understand it than in those who do; but since this view, which Prof. Lloyd Morgan adopts, remains merely adjunct to his evolutionary theme, we propose to turn to the aspect of his work which is of greater biological interest.

The orderly sequence of natural events appears to present, from time to time, something genuinely new. Salient examples are afforded in the advent of life, of mind, and of reflective thought, while in the physical world it is beyond the wit of man to number the instances of "emergence." But if nothing new emerges, "if there be only regrouping of pre-existing events and nothing more, then there is no emergent evolution." Prof. Lloyd Morgan accepts the fact of emergence, and its examples, "with natural piety" (Alexander), which seems to mean little or nothing more than "the frankly agnostic attitude proper to science" (Lloyd Morgan).

Relations in Nature may thus establish additive or resultant characters, productive of quantitative continuity, and coexistent with emergence when it occurs, or emergent characters, which are qualitative, and always involve resultant effects also. In contradistinction to "the mechanistic dogma" the emphasis is not upon physics and chemistry, receptor-patterns and neurone-routes, but upon their "emergents," interrelation, as it were, in ever new relational orders. Modern physics has removed such a conception from the domain of metaphysics, and for better or worse it must be admitted, if not to the bosom, at least to the consideration of naturalism. The break is with vitalism, too, for "if vitalism connote anything of the nature of Entelechy or Elan—any insertion into physico-chemical evolution of an alien influence which must be invoked to explain the phenomena of life—then, so far from this being implied, it is explicitly rejected under the concept of emergent evolution." "Alien influx into nature is barred."

What Prof. Lloyd Morgan claims to be emergent is "some new kind of relation," and all new *kinds* of relation are incapable of prediction. Since relation is "the vaguest term in the philosophical vocabulary," it is well to understand the author's use of it. Relatedness includes not only the relation-of-terms but also the terms-in-relation. An atom is an instance of relatedness; so, too, is an organism. "Any concrete situation in which entities play their part, each in respect of others, is an instance of relatedness." The relations upon which each emergent entity depends are intrinsic; new extrinsic relations accompany its emergence, the two kinds co-existing "inseparably in concrete fact." Change is continuous: "the concrete world we seek to interpret is a going concern; . . . there is a carrying forward of old relations and the emergent advent of new relations."

From this point an effort is made to meet the metaphysical position in regard to the priority of mind to relations. Terms and relations spring into existence together. Throughout his treatment of relatedness, Prof. Lloyd Morgan moves with the New Realists. The heart of the matter for biology lies in what the logicians call the *sense* of relations, deemed here to be determined by natural direction, and in the characters of three-entity situations. Concerning the first, the author sees even in the thought-process a spacial

direction "in the vital and the physical events which are correlated with it." Concerning the second, he says we may have not merely "the additive resultant of this duality *plus* that; but something more in their combination to constitute an integral whole."

Consciousness is to receive further treatment in a second course of lectures, but under the subject of "reference" we have some hints concerning the writer's naturalistic attitude. The analysis of relatedness at the level of consciousness is difficult, because consciousness is a correlate of vital relatedness at a very advanced stage of its evolutionary progress, "requiring the effective go of life as that requires the primary go of physical events, . . . linked with emergent qualities at so high a level, and involving so many kinds of relatedness of lower orders." There follows an able discussion of reference below the level of reflective consciousness, from which Prof. Lloyd Morgan proceeds to his view of "projicience," perceptual reference to a distance (Sherrington), reference of all objective characters to things at a distance (Lloyd Morgan). Projicience, he says, begins "when mind or consciousness is supervenient in the course of evolutionary progress, and takes definite form only when distance-receptors are differentiated on the plane of life. It presupposes the evolution of mind as an emergent quality of the psychical system correlated with the physical system of the organism." Mind is emergent in evolutionary history. When it comes, the "particular go" of events at the level of its advent is altered. This is so with all emergents. "So long as the words are used in a purely naturalistic sense, one may say that the higher kinds of relatedness guide or control the go of lower-level events."—We are not sure that that is not rather a dangerous sentence. What is the naturalistic sense of "guiding" and "controlling"? The question comes back to us in reading the chapter on causation and causality, where Prof. Lloyd Morgan is under some difficulty to rescue the concept of causation (or rather "causality" as better adapted to his theistic position as we understand it) from the clutches of Mach and Bertrand Russell, who both desire the extrusion of the word "cause" from the philosophical vocabulary.

We have neglected the author's theism for the exposition of his naturalism because he himself regards the former as "supplementary." It is to be hoped that impatience with the crudity of much in current biological literature has not closed our eyes to opposite excess in Prof. Lloyd Morgan's work, which, rightly understood, affords encouragement for the rehabilitation of biology on strictly naturalistic lines.

Mathematical Astronomy.

(1) *Cours de mécanique céleste.* Par Prof. H. Andoyer. Tome 1. Pp. vi + 439. (Paris: Gauthier-Villars et Cie, 1923.) 50 francs.

(2) *Cours d'astronomie. Faculté des Sciences de Paris.* Par Prof. H. Andoyer. Première partie: Astronomie théorique. 3ᵉ édition entièrement refondue. Pp. iii + 455. (Paris: J. Hermann, 1923.) 35 francs.

(3) *Grundriss der theoretischen Astronomie und der Geschichte der Planetentheorien.* Von J. Frischauf. Dritte vermehrte Auflage. Pp. xvi + 248. (Leipzig: Wilhelm Engelmann, 1922.)

(1) THE subject of celestial mechanics is distinguished alike by the profound difficulty and the beauty of its problems. For more than two centuries it has been the object of research on the part of the most eminent mathematicians. Its literature, both in the form of theoretical and critical studies and of the most extensive practical calculations ever undertaken, is vast. For the most part the memoirs naturally presuppose a general familiarity with established methods and are concerned with special phases of the subject. They will always leave room for the treatise aiming at a more introductory and systematic exposition. It may appear that in a field so intensively cultivated certain classical lines would have become firmly established, to the exclusion of any fresh and original treatment; that the possibilities open to the writer of a new treatise would have been largely exhausted. That would be to undervalue the richness of the field completely. We are certainly fortunate in the possession of several such systematic treatises, of the highest quality. But when they are brought together, in all languages, they make no excessive number. It is probably safe to assert that no other branch of science is so completely free from superfluous works of this kind. Nor is the reason far to seek. There is no mercenary incentive to their production, and the only motive must be allied with sincerity of purpose.

When therefore Prof. Andoyer modestly refers in his preface to the rashness of his undertaking after the works of Tisserand and Poincaré, he need not be taken seriously at all. Tisserand's is a most beautiful work of exposition, original rather in form than in matter. Poincaré's "Méthodes nouvelles" is a work of original genius, which left its author still free to find independent fields for his "Leçons." The very distance which separates these works in scope and manner would make it strange if they had exhausted the possibilities of the subject for systematic treatment, and it is not true. It is indeed most effectively

disproved by Prof. Andoyer's work, of which the first volume is now published. The author is not only an accomplished mathematician, whose official position places him in direct contact with the work of astronomical computation on the widest scale, but he is also one who has displayed an altogether exceptional faculty in the arid task of calculating mathematical tables. He is therefore in an excellent position to make an instructive contribution to the subject of celestial mechanics, and his work will be received with gratitude.

The present volume is largely concerned with the theory of the determination of orbits. This may suggest comparison with several classical works on that subject. But the treatment it receives here is distinguished by its manner of combining two distinct points of view. The practical nature of the problem is always insisted on, and the needs of the astronomical computer are served by numerical examples drawn from actual practice. At the same time the subject is treated not as a mere precursor, but as an integral part of celestial mechanics. Thus the points of fundamental importance receive a much more critical discussion than has been usual in those treatises which have a more restricted practical outlook. A short digression on the method of least squares is inserted for the determination of a Keplerian orbit based on any number of observations, and a more elaborate section on the theory of interpolation leads up to the calculation of perturbations by numerical quadratures under several forms.

The volume concludes with two chapters, one developing the series relative to elliptic motion and the other dealing with the expansion of the disturbing function, as required in the theory of the major planets. The second volume, which will complete the work, will deal with the theory of the moon, the rotations of the earth and of the moon, and the theory of the Galilean satellites of Jupiter. The whole will form a very valuable contribution to a subject of which the interest, being many-sided, will not easily be exhausted.

(2) Prof. Andoyer's "Cours d'astronomie," of which the first volume now appears in a considerably modified form, has reached its third edition. To this sufficient evidence that it has met with a favourable reception in France, it may be added that it is an excellent example of the class of work to which it belongs. Its subject is what is generally known in England as spherical astronomy, though geometrical astronomy would be a more appropriate name with proper regard to its matter and its methods. The function of such works is to provide for the student, who already possesses the necessary mathematical equipment, an avenue to an exact knowledge of astronomy, apart from any deep acquaintance with celestial mechanics. Thus the contents of the present volume may be summarised under its four sections. The first book provides an introduction to spherical trigonometry and spherical co-ordinates in general. The second introduces the usual systems of astronomical co-ordinates and time, and explains the reductions for refraction, parallax, and aberration. Precession, nutation, and time form the main subjects of the third book, which begins with an outline of the ideas of dynamical astronomy; a complementary chapter on the determination of an orbit from three observations (Lagrange's method) might be transferred from the end of the volume, if indeed the inclusion of this chapter can be justified at all. The fourth and last book deals very fully with the calculation of eclipse phenomena, and the volume ends with a note on the ecclesiastical calendar. It will be seen that these topics mainly follow familiar lines of choice, and, as would be expected from the author, the treatment is throughout sound and scholarly.

Rightly or wrongly, we approach this work from the point of view of the general mathematical student rather than of the professional astronomer. The latter, as a specialist, must be prepared to dig deep for his knowledge. The former will find here a selection of fundamental problems treated with fullness and academic elegance. Whether such a work will inspire him with a true and abiding interest in astronomy appears more doubtful. The author is probably addressing himself to a more advanced type of student than we have in mind, and nothing could be more unjust than to express disappointment with a work on the ground that it does not fulfil a purpose which was never intended by the writer. There is, however, room for an introduction to astronomy addressed to the mathematician who has no professional aim in the science, and for the ideal book of this kind we may still have long to wait.

(3) Dr. Frischauf's work has also reached a third and enlarged edition, but in this case the first edition appeared more than fifty years ago. This vitality it owes to genuine merit, for in a short compass it has provided a succession of German students with a concise and lucid introduction to the problems involved in the determination of orbits. The elementary section on Keplerian motion follows closely the lines of the *Theoria Motus*, and the practical methods which are then explained are those of Olbers for the parabolic orbit and of Gauss for the elliptic orbit. The outlook is thus in a sense restricted, though the modifications introduced by Gibbs are explained and some indication is given of the method of calculating perturbations by mechanical quadratures. But the distinguishing feature of the work lies in its historical sections, which

trace the development of planetary theory from the time of the Greeks through Kepler to Gauss. In no sense is this account complete, any more than that of the modern methods of calculating orbits. It is nevertheless well that the student should have a clear idea of the Ptolemaic system and of the actual steps by which Kepler was led to his epoch-making discoveries. Without its historical background the study of astronomy loses much of its interest, and the realisation of this fact has probably much to do with the continued demand for Dr. Frischauf's book, which is to be inferred from its reappearance. H. C. P.

Medieval Science.

A History of Magic and Experimental Science during the First Thirteen Centuries of our Era. By Prof. Lynn Thorndike. Vol. 1. Pp. xi+835. Vol. 2. Pp. vi+1036. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1923.) 2 vols., 10 dollars. 42s. net.

THE very important work recently issued by Prof. Thorndike is a monument of learning scientifically marshalled. It marks a period in the history of medieval studies, which it will influence in somewhat the same way that anthropology has been affected by "The Golden Bough," a book with which it has many parallels. Prof. Thorndike has produced a work which in every sense is worthy of the name of "scientific." He carries on the exploration of magical ideas beyond the level of civilisation at which anthropologists are accustomed to stop, and he demonstrates the same ideas current in the highly sophisticated atmosphere of the scholastic Middle Ages.

From the title over the introduction to the work, namely, "A History of Magic and Experimental Science and their Relation to Christian Thought," etc., the reader might be led to expect a polemical exposition of a definite point of view towards some of the great problems of human existence. Prof. Thorndike, however, presents us with an immense collection of facts with the object of adding to our knowledge of the history of thought, rather than of proving any previously formulated thesis. "Magic," "Experimental Science," "Christian Thought" are rather chosen as headings to help the student towards evolving some order in the mass of material. The conceptions expressed by each of these modern terms can in turn throw a further light on the history of thought, for it is ideas rather than the practices to which they lead on which Prof. Thorndike has focussed his discussion. "Magic represented a way of looking at the world. In the case of primitive men and savages it is possible that little thought accompanied their action." But until such thought develops a purposive and rational basis, the doings of man cannot be distinguished as either religious or scientific or magical. Even magic implies such purposive mental states, and so may be viewed from the point of view of the history of thought.

An attempt is made to trace a relationship of some of the most important manifestations of mental life during the long period under consideration. Thus in one age Prof. Thorndike finds the germ of conceptions more fully developed by another generation, and gradually undergoing profound modification through succeeding years. More than half of the work deals with the twelfth and thirteenth centuries, but the author fully justifies his contention that this period can only be understood when viewed as the outcome of Greek, Latin, and early Christian thought.

The broad survey of the book enables us to consider human thought throughout the period considered as something like an organic whole. The sense of continuity and interrelationship is strong throughout. "It seems to me," says Prof. Thorndike, "that in the present stage of research into and knowledge of our subject, sounder conclusions and even more novel ones can be drawn by a wide comparative survey than by a minutely intensive and exhaustive study of one man or of a few years." It would be a mistake, however, to think that no intensive study has gone to the preparation of these volumes. They are indeed a mine of erudition, and will be indispensable for reference by all who have to treat of medieval life or thought. They present a repertory of what is known as to the lives and works of an immense number of Western writers up to the fourteenth century, and an invaluable record of the whereabouts of much unpublished material scattered throughout the great libraries of Europe. Nor is the study limited to well-known names. Thus, the reviewer has long been interested in an obscure text of English origin known as the "Secreta Philosophorum," which combines in heterogeneous fashion technical and chemical recipes, conjuring tricks and riddles, mathematical and musical lore, and astronomy. This entertaining work, though it enjoyed considerable popularity in fourteenth- and fifteenth-century England, has hitherto been overlooked by medievalists. But it has not escaped the vigilance of Prof. Thorndike, who gives an interesting and succinct account of its contents, and has observed that it embodies a composition by the thirteenth-century Italian writer, Peter the Pilgrim, on the magnet and its use as a compass. The point is of some importance, as Peter Peregrinus was the first writer on the mariner's compass whose works have come down to us.

This stray example could no doubt be paralleled by the experience of many students who will find in Prof.

Thorndike's pages material throwing light on their own special studies. Medieval students may indeed be congratulated on the appearance of a work which will lighten their labours and illumine their path. Nor is it only the specialist to whom it will appeal. Many are puzzled by the extravagant claims sometimes made to-day for the "Middle Ages." An attempt to penetrate the mass of medieval literature will probably produce a strong reaction from any such conceptions, but the ordinary reader is liable to retire vanquished before he has covered a tithe of the material or gained any broad view of its course. Such readers will be grateful to find in these volumes a thoroughly readable presentation of medieval thought, while every page provides evidence of the sources where each statement may be verified. The admirably full and well-arranged indices are a very welcome element. Prof. Thorndike's work undoubtedly takes rank as an important contribution to the history of civilisation.

DOROTHEA WALEY SINGER.

Chemical Works of Reference.

(1) *A Comprehensive Treatise on Inorganic and Theoretical Chemistry.* By Dr. J. W. Mellor. Vol. 3: *Cu, Ag, Au, Ca, Sr, Ba.* Pp. x+927. (London: Longmans, Green and Co., 1923.) 63*s.* net.

(2) *A Dictionary of Applied Chemistry.* By Sir Edward Thorpe. Vol. 4: *L-Oxydisilin.* Revised and enlarged edition. Pp. viii+740. (London: Longmans, Green and Co., 1922.) 60*s.* net.

(3) *Text-book of Inorganic Chemistry.* Edited by Dr. J. Newton Friend. Vol. 9, Part 1: *Cobalt, Nickel, and the Elements of the Platinum Group.* By J. Newton Friend. (Griffin's Scientific Text-books.) Second edition, revised. Pp. xxv+367. (London: C. Griffin and Co., Ltd., 1922.) 18*s.* net.

(1) THE third volume of Dr. Mellor's great treatise deals with the two triads, copper, silver, gold, and calcium, strontium, barium. In a work of reference the order in which the elements are taken is of less importance than in a text-book, but the scheme adopted in this volume has certain disadvantages. By considering the alkaline earths as a group, the author has been able to bring together on one page the ternary diagrams for the systems $CaO-CaCl_2-H_2O$, and $SrO-SrCl_2-H_2O$, and in general has secured the advantage of being able to describe the strontium and barium salts as variants of the more familiar calcium salts; but this close association of the metals of the three alkaline earths makes it all the more remarkable that the element magnesium is not even included in the same volume, so that magnesite and calcite are separated as widely as possible from one another. The interpolation of copper, silver, and gold between the alkalies and the alkaline earths is, of course, a concession to the law of octaves as expressed in Mendeléeff's series of thirteen short periods.

In addition to the disadvantage of separating the alkalies and the alkaline earths, the arrangement suffers from the drawback that copper, silver and gold may be regarded as forming a first stage in the winding up of the anomalies of the metals of the transition series. They therefore exhibit, in an attenuated form, the influence of the phenomena of co-ordination, which dominates so fully the chemical properties of the elements which immediately precede them in the periodic classification. It is therefore a real disadvantage that the wide range of amines and of double salts which are formed by these metals are described at a stage when the theory of co-ordination has not yet been discussed.

In his preface the author states that he has been much pleased with the general reception which the first two volumes have received. The reviewer can confirm from his own experience the value of the author's treatise, even at the present stage, when scarcely half of the work is available for reference, and is confident that the treatise when complete will be of very great service to all serious students of inorganic chemistry.

(2) The fourth volume of the new edition of the "Dictionary of Applied Chemistry" covers the section from L to O, with the exception that the articles on oxygen, ozone, etc., are held over for a later volume. In the section now published there has been a considerable expansion, from 600 to 740 pages. While most of the principal articles in the volume have contributed something to this increase of length, the most notable changes are to be found in the series of articles under the heading "Nitrogen." The article on nitrogen itself does not appear to have been altered very greatly; but in writing the section on the manufacture of nitric acid, Prof. Hart has secured the collaboration of Dr. F. C. Zeisberg, of Du Pont de Nemours and Company, and a completely new series of diagrams is given to illustrate modern practice in the manufacture of this acid. In addition to this, the earlier article on the utilisation of atmospheric nitrogen has been replaced by an article of nearly three times the length by Prof. J. R. Partington, in which a much fuller account is given of the various processes for the fixation of nitrogen and of the methods used for the oxidation of ammonia to nitric acid.

(3) The second edition of Dr. Friend's text-book requires only brief comment, since very little alteration has been made in the book, apart from the addition of some notes on the detection and estimation of the platinum metals. It is, however, noteworthy that the

periodic table, which forms the frontispiece of the volume, does not give the atomic numbers of the elements—an omission which should certainly be rectified when a further edition of any of these volumes is called for. The value of this particular volume would also be much increased by a fuller appreciation of the part played by co-ordination in the formation of so many of the compounds of this group of elements.

Our Bookshelf.

Electrons, Electric Waves and Wireless Telephony: Being a Reproduction with some Amplification of the Christmas Lectures (96th Course) delivered at the Royal Institution of Great Britain, December, 1921, January, 1922. By Prof. J. A. Fleming. Pp. viii + 326. (London: The Wireless Press, Ltd.; New York: The Wireless Press, Inc., 1923.) 7*s.* 6*d.* net.

Simple and excellent descriptions are first given of the phenomena which take place when waves are produced in liquids and gases. The author then gives an account of the architecture of atoms as imagined by modern physicists. The Rutherford atom is taken as the standard and the Planck-Bohr method, in which atoms are supposed to radiate energy, is described. The concluding portion of the book is on radio-telephony and will be very helpful to the intelligent amateur.

Prof. Fleming's discussions are on orthodox lines, but we were disappointed that he does not throw more light on the mechanism of Planck's quantum theory. Many of the numerical results obtained are wonderful and are corroborated in the most marvellous way by other methods. But the *modus operandi* is still a mystery. In describing the Michelson-Morley experiment it is stated that it proves clearly that the velocity of light is independent of the motion of the source of light or of the observer. We are not justified, however, in accepting this statement if an explanation can be given which satisfies the accepted canons of mechanical science. Such an explanation was given by Fitzgerald. The dragging in of space and time "frames of reference" does not help the ordinary reader. We are glad the author adheres as far as possible to the laws of classical dynamics. Some men of science are wondering how much of modern theory will remain when all the laboriously constructed scaffolding is removed.

Poems of Science: Pages of Indian Earth History. By K. A. Knight Hallowes. Pp. xii + 40. (London: Erskine Macdonald, 1923.) n.p.

Mr. K. A. Knight Hallowes has worked for eighteen years on the staff of the Geological Survey of India, and the beauty and dignity of the country that he has studied have appealed to his poetic sense. In a series of sonnets, he touches on the origins and the decay of the rocks that control some of the noblest scenery of the earth; and again and again the bright hue of a delicate flower, springing from some cleft in a forbidding plateau or a torrent-carved ravine, lifts his thoughts from the earth to the great Mystery that is worshipped under many names. We must not expect Wilde's

> O lonely Himalayan height,
> Grey pillar of the Indian sky,

or

> The almond groves of Samarcand,
> Bokhara, where red lilies blow;

but we cannot help remembering what use Marlowe made of the resonant names that reached him from the East. Mr. Hallowes does not rise above the Gazetteer of India with such lines (p. 23) as "In Burma, in the district of Magwe." The seventh sonnet shows, however, that he has achieved a mastery over a difficult form of verse, and the simple opening lines, oddly enough recalling Dante, lead on to effective geological expression at the close. Elsewhere the "science" is a little clouded by such phrases as "molten fire" and "powers exhibited by flame in bygone time." The eleven words describing foliation in Sonnet XV. are accurate enough, but leave the layman somewhat cold.

Ergebnisse der exakten Naturwissenschaften. Herausgegeben von der Schriftleitung der *Naturwissenschaften.* Pp. iv + 403. (Berlin: Julius Springer, 1922.) 10*s.* 5*d.*

The first annual volume of this new review of the exact natural sciences covers an immense territory in a very thorough manner; and it is evident that this, and the future volumes, will be an essential requisite in every physical library. Astronomy, relativity, statistical mechanics, the vibrations of rotating shafts, Nernst's thermal law, radiation, contact potential, chemical kinetics, photochemistry, electrolytic dissociation, X-ray spectroscopy, crystal structure, atomic and spectral theory, the theory of band spectra, photoelectricity and photoluminescence, and the periodic system of the elements are treated by authorities who have contributed to the recent remarkable developments of the subjects with which they deal. In this initial volume most of the reviewers have attempted to give a general account of the present state of the subjects reviewed, and the bibliographies which accompany their papers appear to be very comprehensive. The latter should prove very valuable; they cover the ground up to 1922, and include work by English and American physicists, the value of which is fully recognised in the text. Future volumes will be devoted more specifically to progress made during the year under review, the object being to give a general view of the progress made without details of individual publications.

Opere di Paolo Celesia. Serie scientifica a cura di F. Raffaele della R. Università di Roma. Studi biologici. Con prefazione di Osvaldo Polimanti. Pp. xii + 426. (Roma: Dr. G. Bardi, 1923.) n.p.

Paolo Celesia was born at Genoa in 1872 and died in Rome in 1916. He was attracted to the study of natural science and began his scientific training in the laboratory of comparative anatomy in Genoa, and soon took up the investigation of the sponge Suberites and its symbiosis with the hermit crab Pagurus, his account of which forms the first paper

in this volume. He then turned to experimental work on the ventral nerve-cord of the rock-lobster Palinurus, and on the reflex mechanism of the chela of the crayfish. He built a private laboratory on the shore of Lake Como, but his scientific work was interrupted by another project—he founded the *Rivista di Scienze biologiche* and wrote for it many critical articles and reviews. The death of his father and of his faithful laboratory assistant caused him to suspend his researches, and he turned largely to philosophy. His friends have decided to reprint a selection of his earlier papers and of his unpublished work, and the present volume, which is excellently produced, forms the first instalment. It consists of eleven original papers—on the subjects noted above and on graft hybrids, their significance in regard to heredity and acquired characters, the transformation of the wild bee into the hive bee, etc.—sixteen reviews and articles, and a reprint of his thesis on progressive heredity.

Handbuch der Zoologie: eine Naturgeschichte der Stämme des Tierreiches. Begründet von Prof. Dr. Willy Kükenthal. Herausgegeben von Dr. Thilo Krumbach. Erster Band: Protozoa, Porifera, Cœlenterata, Mesozoa. Erste Lieferung. Pp. 192. (Berlin und Leipzig: Walter de Gruyter und Co., 1923.) 9*s.*

THIS forms the first part of Vol. I. of a handbook of zoology, to be completed in five volumes, in the preparation of which about forty authors have agreed to take part. An introduction (50 pp.) to the Protozoa by Prof. Rhumbler is followed by an account (60 pp.) of the Rhizopoda by the same author and of the Flagellata by Dr. V. Jollos, and by the first few pages of the section on the Sporozoa by Prof. M. Hartmann. After the general account of each order is given a scheme of classification into sub-orders, groups, families, and, in some cases, genera, with short diagnoses of each. While the treatment of most of the groups is adequate, the very brief account of Entamœba is not consonant with the importance of this genus, of which no figure is given. The latest references in the list of works on Rhizopoda relate to papers published in 1916, and this suggests that publication has been delayed. The section on the flagellates contains a number of good new figures, and the list of references includes papers published in 1921 and 1922, but the account of the collared flagellates is very short and inadequate.

Plane Geometry for Schools. By T. A. Beckett and F. E. Robinson. Part II., with Answers. Pp. viii + 241-453 + v. (London: Rivingtons, 1922.) 5*s.*

MESSRS. Beckett and Robinson's interesting attempt to combine the main propositions of formal geometry with the extensions included in the easier portions of "modern plane geometry" and with the fundamental notions and applications of trigonometry, is continued in the second part of their work. The first part was noticed in these columns on June 10, 1922 (vol. 109, p. 737). The second part consists of three sections. Section iv. deals with areas, extensions of Pythagoras's theorem, and the properties of chords and tangents of circles, with incidental reference to radical axis, graphical solution of quadratic equations, etc. In section v. we have inequalities, maxima and minima, and regular polygons. Section vi. deals with ratio and proportion: applications to trigonometry are then given, as well as centres of similitude, inversion, pole and polar (with a little on anharmonic ratio). The treatment is pleasant and masterly, and the whole work can be highly recommended. S. B.

Printing Telegraph Systems and Mechanisms. By H. H. Harrison. (Manuals of Telegraph and Telephone Engineering.) Pp. xii + 435. (London: Longmans, Green and Co., 1923.) 21*s.* net.

THIS volume will be most useful as a work of reference to designers of telegraph machinery. It will also be useful as a text-book in telegraph administrations. The book has been very carefully compiled; the diagrams, of which there are 420, are excellent, and the latest modern applications including high frequency multiplex methods, both for land and submarine cables, are fully described. There is now considerable overlapping of the sciences of telephony, telegraphy and radio-communication, many of the same devices being used in each. It must be admitted that at present, development in all branches of the art of communication is taking place most rapidly in the United States. Communication service in that country is such a large undertaking that systematic research can be carried on intensively on a scale that excites the wonder and envy of European engineers. In Britain, the home demand for apparatus is comparatively on a much smaller scale.

Experimental Physical Chemistry for Students in the Medical and Allied Services. By Dr. B. S. Neuhausen. Pp. 53. (Philadelphia: H. N. Rudley, 614 Arch Street, 1923.) 1 dollar.

DR. NEUHAUSEN'S work is in the form of a pamphlet rather than of a book. The physio-chemical exercises which he describes are all related directly to biochemistry or medicine; thus, measurements of freezing-point depression, electrical conductivity, the concentration of hydrogen, sodium and chlorine ions, viscosity, refractive index, etc., are all carried out with serum rather than with more commonplace solutions; and the rate of inversion of cane-sugar is studied in the form of an inversion by invertase in place of the more familiar inversion by acids. In view of the growing importance of physical measurements in biochemistry the appearance of a work of this character may be heartily welcomed.

A Text-book of Physics. By Dr. R. S. Willows. Third edition. Pp. viii + 48 + 488. (London: E. Arnold and Co., 1923.) 9*s.* net.

THE call for the third edition of this useful text-book has given the author an opportunity to add a chapter on the conduction of electricity through gases. The McLeod gauge is first described and a brief account is given of the electric discharge in a vacuum tube. Then follow experiments on kathode rays and positive rays, and paragraphs dealing with X-rays, ionisation in gases and radioactivity. A chapter of a similar kind on electromagnetic waves may be suggested for a future edition.

Letters to the Editor.

Psycho-Analysis and Anthropology.

THE infection by psycho-analysis of the neighbouring fields of science—notably that of anthropology, folklore, and sociology—has been a very rapid and somewhat inflammatory process. The votaries of Freud, or some among them, have displayed in their missionary zeal an amount of dogmatism and of aggressiveness not calculated to allay the prejudice and suspicion which usually greet every new extension of their theories. Some of their critics, on the other hand, go so far as to dismiss all anthropological contributions of Freud and his school as "utterly preposterous" and "obviously futile," as "an intrigue with Ethnology which threatens disaster to both parties," as "a striking demonstration of *reductio ad absurdum*" (Prof. Elliot Smith in Rivers's "Psychology and Politics," pp. 141-145). This is a harsh judgment and it carries much weight, coming from one by no means hostile to psycho-analysis and thoroughly well acquainted with anthropological problems, especially those discussed by Freud and his school. This seems the right moment to consider impartially, without enthusiasm or prejudice, the scope, importance, and value of Freud's contribution to anthropology.

Through the initiative and under the direction of Prof. Seligman, who at that time was engaged in practical psycho-analysis of war neuroses, I have been able to apply some of Freud's conclusions directly to savage psychology and customs, while actually engaged in field-work among the natives of Eastern New Guinea.

Freud's fundamental conception of the Œdipus complex contains a sociological as well as a psychological theory. The psychological theory declares that much, if not all of human mental life has its root in infantile tendencies of a "libidinous" character, repressed later on in childhood by the paternal authority and the atmosphere of the patriarchal family life. Thus there is formed a "complex" in the unconscious mind of a parricidal and "matrogamic" nature. The sociological implications of this theory indicate that throughout the development of humanity there must have existed the institution of individual family and marriage, with the father as a severe, nay, ferocious patriarch, and with the mother representing the principles of affection and kindness. Freud's anthropological views stand and fall with Westermarck's theory of the antiquity and permanence of individual and monogamous marriage. Freud himself assumes the existence at the outset of human development, of a patriarchal family with a tyrannical and ferocious father who repressed all the claims of the younger men (*cf.* "Totem and Taboo," chap. iv. 5, and "Massen-Psychologie und Ich-Analyse," chap. x.). With the hypothesis of a primitive promiscuity or group marriage, Freud's theories are thoroughly incompatible, and in this they have the support, not only of Westermarck's classical researches, but also of the most recent contributions to our knowledge of primitive sexual life.

When we come to examine in detail the original constitution of the human family—not in any hypothetical primeval form, but as we find it in actual observation among present-day savages—some difficulties emerge. We find, for example, that there is a form of matriarchal family in which the relations between children and progenitors do not exist in the typical form as required by Freud's hypothesis of the Œdipus complex. Taking as an example the family as found in the coral archipelagoes of Eastern New Guinea, where I have studied it, the mother and her brother possess in it all the legal *potestas*. The mother's brother is the "ferocious matriarch," the father is the affectionate friend and helper of his children. He has to win for himself the friendship of his sons and daughters, and is frequently their amicable ally against the principle of authority represented by the maternal uncle. In fact, none of the domestic conditions required for the sociological fulfilment of the Œdipus complex, with its repressions, exist in the Melanesian family of Eastern New Guinea, as I shall show fully in a book shortly to be published on the sexual life and family organisation of these natives.

Again, the sexual repression within the family, the taboo of incest, is mainly directed towards the separation of brother and sister, although it also divides mother and son sexually. Thus we have a pattern of family life in which the two elements decisive for psycho-analysis, the repressive authority and the severing taboo, are "displaced," distributed in a manner different from that found in the patriarchal family. If Freud's general theory is correct, there ought to be also a change in the thwarted desires; the repressed wish formation ought to receive a shape different from the Œdipus complex.

This is as a matter of fact what happens. The examination of dreams, myths, and of the prevalent sexual obsessions reveals indeed a most remarkable confirmation of Freudian theories. The most important type of sexual mythology centres round stories of brother-sister incest. The mythical cycle which explains the origin of love and love magic attributes its existence to an act of incest between brother and sister. There is a notable absence of the parricidal motive in their myth. On the other hand the motive of castration comes in, and it is carried out not on the father but on the maternal uncle. He also appears in other legendary cycles as a villainous, dangerous, and oppressive foe.

In general I have found in the area of my studies an unmistakable correlation between the nature of family and kinship on one hand and the prevalent "complex" on the other, a complex which can be traced in many manifestations of the folklore, customs, and institutions of these natives.

To sum up, the study of savage life and some reflection on Freud's theories and their application to anthropology have led me to the conviction that a great deal of these theories requires modification and in its present form will not stand the test of evidence—notably the theory of *libido*, the exaggeration of infantile sexuality, and the manner in which "sexual symbolisation" is dealt with. The character of the argumentation and the manner and mannerisms of exposition moreover often contain such glaring surface absurdities and show such lack of anthropological insight that one cannot wonder at the impatience of a specialist, such as expressed in the remarks of Prof. Elliot Smith quoted above. But with all this, Freud's contribution to anthropology is of the greatest importance and seems to me to strike a very rich vein which must be followed up. For Freud has given us the first concrete theory about the relation between instinctive life and social institution. His doctrine of repression due to social influence allows us to explain certain typical latent wishes or "com-

plexes," found in folklore, by reference to the organisation of a given society. Inversely it allows us also to trace the pattern of instinctive and emotional tendencies in the texture of the social fabric. By making the theories somewhat more elastic, the anthropologist can not only apply them to the interpretation of certain phenomena, but also in the field he can be inspired by them in the exploration of the difficult borderland between social tradition and social organisation. How fruitful Freud's theories are in this respect I hope to demonstrate clearly in the pending publication previously mentioned.

Spectra of Isotopes.

THE quantum theory of line spectra developed by Bohr has been most successful in explaining the spectrum of hydrogen and helium, and by a further hypothesis the spectra of the alkali metals. By asserting that elliptic orbits are possible, as well as circular orbits, Sommerfeld succeeded in explaining the Stark and Zeeman effects and the fine structure of spectral lines. It is significant that Bohr's equation for the frequency of the spectral series also explains the difference between the series spectra of isotopes of the same element. The experiments of Aronberg and Merton on the structure of 4058 Å. of isotopes of lead showed, however, a remarkable discrepancy between the shift predicted by the theory and that actually observed. Similarly Merton's experiments on the line 6708 of lithium showed that the line consisted of two components 0·151 Å. apart, while the theoretical shift was 0·087 Å. The quantum theory is unable to account for this large separation observed.

Recently Ehrenfest, commenting upon the validity of the simple Bohr equation, remarked that the equation cannot be true in general for atoms with several electrons, as in this case the radiating electron compels the remaining electrons to execute the motions of reaction which influence the nucleus. Moreover, Nicholson has shown that, by the choice of simpler orbits and by the supposition made by Sommerfeld, as to invariability of energy W for all possible orbits, the inner orbit has a radius of about one-tenth of that of the outer orbit. It has thus been shown that the external electron moves in the field of the nucleus, which is asymptotically a Coulomb field, and that Bohr's formula cannot be far wrong for a rough determination of the separation to be looked for in the spectra of isotopes.

Prof. McLennan, however, in an account of interesting experiments (Proc. Roy. Soc. A 714, p. 33, and A 711, p. 342) on the structure of the line 5460 of mercury and the line 6708 of lithium, and isotope displacement, has found that when the radiation constituting the green line of mercury is passed through moderately luminous vapour, the main component and components $+1$ and -1 are distinctly absorbed. In an attempt to explain the complex structure of the lines from the point of view of the isotopic structure of the elements, the view is put forward that the spectral displacement for isotopes should be given by the atomic number multiplied by the displacement calculated on Bohr's theory, and the main components of 5460 are attributed to isotope 200, and the component $+1$ and -1 to isotopes 198 and 202 respectively.

In the light of the recent experiments of Bronsted and Hevesy, who succeeded in separating the isotopes of mercury, and showed also that the isotopic composition of mercury of terrestrial origin is the same, it is difficult to conceive why, in Prof. McLennan's experiments, the lines corresponding to isotopes 198, 200 and 202 should alone be absorbed, while the lines corresponding to the other isotopes are not absorbed. Further, if, according to Aston's experiments, isotopes 197–200 exist in mercury in largest proportion, one would naturally expect that the most intense component of 5460, that is, the main component, should naturally correspond to isotope 197. Similarly in the case of lithium, he found that the line 6708 consists of a quartet, the average displacement of one doublet being about 3 to 4 times as great as the calculated separation, namely, 0·087. But generally it is found that enhanced lines are developed when an arc is operated in vacuo, thereby showing that it cannot be supposed that these lines are true arc lines, which is in conformity with Nicholson's view that the radiation 6708, which McLennan examined, might be the principal spark line of lithium, which has a value very close to 6708.

These facts naturally lead one to question whether McLennan's view has real physical significance. To settle this point a careful examination of the structure of some bright line spectra was undertaken in this laboratory. The most recent experiments of Aston (*Phil. Mag.*, May 1923, p. 934) have definitely established that tin is a highly complex element, being a mixture of eight isotopes of atomic weights 120, 118, 116, 124, 119, 117, 122 and 121, in which case the isotope displacement for 5631, for isotopes 120 and 124, and 120 and 116, is roughly equal to $\pm 0{\cdot}0007614$, that is, for 116 and 124, 0·001523; while according to McLennan's view it is equal to 0·03807 and 0·07614, which is well within the limits of resolution of an ordinary Lummer plate or Fabry Perot etalon. Therefore the structure of the lines 5631 and 4524 was carefully examined by a Lummer plate, the R.P. of which for 5631 = 250,000. In these experiments the arc was enclosed in a chamber surrounded by a water jacket, and the radiation from the arc was examined at different pressures. It was found that even when the pressure was low (that is, of the order of 1 mm.) both the lines were simple in structure, especially the line 4521, which was very sharp. These experiments do not, therefore, support the view put forward by McLennan.

A Substitute for the McLeod Gauge.

ALTHOUGH numberless accounts have appeared of the precautions necessary in the obtaining of high vacua, some serious workers seem still to imagine that they can reach "a perfect vacuum" or "a pressure of 0·001 mm." in an apparatus from which absorbed water has not been removed. The lingering of this ancient superstition is due to the prevalence of the McLeod gauge; if any gauge which indicates vapours as well as permanent gases had been in general use, it could never have arisen. Historians may dispute whether the invention of the McLeod gauge has advanced or retarded the development of science; but there is no doubt that to-day, though it may have special uses (such as the calibration of other gauges) under rigidly controlled conditions, it is usually a mere relic of the past.

Compared with its adequate substitutes the McLeod gauge has not even the merit of convenience. In particular, although some workers who are perfectly aware of its limitations continue to make it a normal component of any pumping system, it is not the most

convenient gauge even for such a commonplace purpose as detecting leaks and ensuring generally that the system is in good order. We think we may be doing some service to our colleagues if we urge on them the advantages for this purpose of the Pirani gauge, especially if used according to the method that the staff of these laboratories described (but did not discover) in Physical Society Proceedings, vol. 33, p. 287, 1921.

The great advantage of this instrument is its magnificent simplicity. In addition to some very ordinary electrical gear—a battery, rheostat, 3 fixed resistance coils adjusted very roughly, a cheap pointer galvanometer, and a respectable voltmeter—it needs nothing but an ordinary incandescent vacuum lamp. Since lamps are cheap and since the same electrical gear will serve any number of lamps, there is no limit to the number of gauges which can be readily attached to the same piece of apparatus. The diagnosis of leaks and other faults is a very simple matter when gauges are attached at almost every joint, and their readings with the pump running are compared. But this is not its only virtue. We are certain that any one who tries the Pirani gauge will forthwith consign his McLeod gauge to the dust heap and wonder how he ever managed with such a cumbrous and misleading device.

It is sometimes objected to all gauges but the McLeod, that their calibration depends on the nature of the gas. To this we would reply that in every experiment we can imagine in which a knowledge of the *absolute* value of the pressure is required, either the nature of the gas is known or it has to be determined for some purpose other than that of reading the gauge.
